# Abstract

Microfluidic biochips have now come of age, with applications to biomolecular recognition for high-throughput DNA sequencing, immunoassays, and point-of-care clinical diagnostics. In particular, digital microfluidic biochips, which use electrowetting-on-dielectric to manipulate discrete droplets (or “packets of biochemical payload”) of picoliter volumes under clock control, are especially promising. The potential applications of biochips include real-time analysis for biochemical reagents, clinical diagnostics, flash chemistry, and on-chip DNA sequencing. The ease of reconfigurability and software-based control in digital microfluidics has motivated research on various aspects of automated chip design and optimization.

This thesis research is focused on facilitating advances in on-chip bioassays, enhancing the automated use of digital microfluidic biochips, and developing an “intelligent” microfluidic system that has the capability of making on-line re-synthesis while a bioassay is being executed. This thesis includes the concept of a “cyberphysical microfluidic biochip” based on the digital microfluidics hardware platform and on-chip sensing technique. In such a biochip, the control software, on-chip sensing, and the microfluidic operations are tightly coupled. The status of the droplets is dynamically monitored by on-chip sensors. If an error is detected, the control software performs dynamic re-synthesis procedure and error recovery.

In order to minimize the size and cost of the system, a hardware-assisted error-recovery method, which relies on an error dictionary for rapid error recovery, is also

presented. The error-recovery procedure is controlled by a finite-state-machine implemented on a field-programmable gate array (FPGA) instead of a software running on a separate computer. Each state of the FSM represents a possible error that may occur on the biochip; for each of these errors, the corresponding sequence of error-recovery signals is stored inside the memory of the FPGA before the bioassay is conducted. When an error occurs, the FSM transitions from one state to another, and the corresponding control signals are updated. Therefore, by using inexpensive FPGA, a portable cyberphysical system can be implemented.

In addition to errors in fluid-handling operations, bioassay outcomes can also be erroneous due to the uncertainty in the completion time for fluidic operations. Due to the inherent randomness of biochemical reactions, the time required to complete each step of the bioassay is a random variable. To address this issue, a new “operation-interdependence-aware” synthesis algorithm is proposed in this thesis. The start and stop time of each operation are dynamically determined based on feedback from the on-chip sensors. Unlike previous synthesis algorithms that execute bioassays based on pre-determined start and end times of each operation, the proposed method facilitates “self-adaptive” bioassays on cyberphysical microfluidic biochips.

Another design problem addressed in this thesis is the development of a layout-design algorithm that can minimize the interference between devices on a biochip. A probabilistic model for the polymerase chain reaction (PCR) has been developed; based on the model, the control software can make on-line decisions regarding the number of thermal cycles that must be performed during PCR. Therefore, PCR can be controlled more precisely using cyberphysical integration.

To reduce the fabrication cost of biochips, yet maintain application flexibility, the concept of a “general-purpose pin-limited biochip” is proposed. Using a graph model for pin-assignment, we develop the theoretical basis and a heuristic algorithm to generate optimized pin-assignment configurations. The associated scheduling algorithm

for on-chip biochemistry synthesis has also been developed. Based on the theoretical framework, a complete design flow for pin-limited cyberphysical microfluidic biochips is presented.

In summary, this thesis research has led to an algorithmic infrastructure and optimization tools for cyberphysical system design and technology demonstrations. The results of this thesis research are expected to enable the hardware/software co-design of a new class of digital microfluidic biochips with tight coupling between microfluidics, sensors, and control software.

Dedicated to my beloved grandfather and grandmother, Junyi Luo and Fangzhen  
Wang

1.10	Comparison between the conventional design flow and the chip-level biochip design flow [39]. . . . .	16
2.1	(a) Initial sequencing graph; (b) operations 12, 13, and 14 are added for error recovery. . . . .	24
2.2	The schematic of the cyberphysical digital microfluidic system. . . . .	25
2.3	Illustration of a digital microfluidics-based image processing system [52]. . . . .	26

2.4	(a) The matching process moves the template image to all possible positions in a larger source image and computes a numerical index that indicates how well the template matches the sub-image in that position; (b) the image of the whole biochip [53] and the pattern we selected; (c) the correlation map between image of the whole array and the pattern. The positions of droplets can be determined by finding $\kappa$ maximum elements ( $\kappa$ is the number of droplets on the chip) in the correlation map. . . . .	28
2.5	The schematic of the cyberphysical digital microfluidic system. Software running on the computer and the biochip are coupled by a field-programmable gate array (or a single-board microcontroller) and peripheral circuit. . . . .	30
2.6	(a) An example of a sequencing graph corresponding to a bioassay protocol; (b) the layout of a biochip with reserved area for error recovery.	32
2.7	Pseudocode for determining the recovery operation for $opt_i$ . . . . .	35
2.8	(a) An error caused by the phenomenon of charge trapping; (b) splitting operation with droplets with unbalanced volumes; (c) an error caused by DNA fouling on the surface of a biochip. . . . .	36
2.9	Pseudocode for adjustment of the sequencing graph. . . . .	40
2.10	Update of the sequencing graph corresponding to error operations of Categories (a) I; (b) II; and (c) III. . . . .	41
2.11	Pseudocode for dynamic re-synthesis of the bioassay. . . . .	44
2.12	(a) Scheduling result when no error occurs; (b) scheduling when an error occurs in Mix 3. Mix 1 is halted when error operations are executed; (c) scheduling when an error occurs in Mix 3. Here dynamic synthesis strategy is applied at time 10 and error recovery operations begin at time 11. . . . .	45
2.13	Sequencing graph for sample preparation of plasmid DNA. . . . .	47
2.14	Completion time for biochip with CCD camera-based sensing system, and the biochip without error recovery mechanism when errors are injected in the sample preparation of plasmid DNA. . . . .	48

2.15	Comparison for the completion time between reliability-driven and reliability-oblivious error recovery [51] when a $1 \times 4$ subarray is defective in the sample preparation of plasmid DNA. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in simulation. . . . .	48
2.16	Comparison between the completion time of reliability-driven and reliability-oblivious error recovery when a $2 \times 4$ subarray is defective in the sample preparation of plasmid DNA. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in simulation. . . . .	49
2.17	Completion time for biochips with CCD camera-based sensing systems and without error recovery mechanism when errors are injected in the sample preparation of interpolating mixing. . . . .	50
2.18	Completion time for the bioassay of interpolating mixing (derived from two re-synthesis algorithms when multiple errors are injected). . . . .	51
2.19	Comparison between the completion time of reliability-driven and reliability-oblivious error recovery [51] when a $1 \times 4$ defect array is injected in exponential dilution. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in the simulation. . . . .	53
3.1	The proposed finite-state machine control system implementation of the cyberphysical system. The FSM runs on the microcontroller or the FPGA, and its current state determines control signals applied on the biochip. A state transition of the FSM is triggered by the detection of error(s). . . . .	58
3.2	Tree structure of the error dictionary. Entries at the $k^{\text{th}}$ level of the dictionary correspond to all possible cases of errors that can occur involving $k$ operations. . . . .	60
3.3	Module placement for the bioassay shown in Figure 2.1(a). . . . .	61
3.4	Movement of droplets for (a) mixing; (b) splitting; (c) dispensing [16]. Step <i>A</i> to Step <i>D</i> show the procedure of pulling a droplet from the reservoir. . . . .	67
3.5	Modules and their interconnections for the dictionary-based error recovery system. . . . .	73

3.6	Splitting of a droplet: Both Electrode 1 and Electrode 3 are actuated, and electrowetting forces are generated on the surfaces of these two electrodes. . . . .	77
3.7	(a) The histogram for the number of extra droplets consumed in all possible situations of exponential dilution bioassay; (b) the histogram for the time spans of effective dictionary entries when $N_{max} = 5$ . . . .	80
3.8	(a) The histogram for the numbers of extra droplets consumed in the 233 runs in which 233 errors are generated; (b) the histogram for the time spans of entries in the 233 runs in which errors are generated. . .	84
3.9	(a) The histogram for the numbers of extra droplets consumed in all possible situations of the interpolation-based dilution bioassay; (b) the histogram for the time spans of entries in the error dictionary for the interpolation-based dilution bioassay (when $N_{max} = 3$ ). . . . .	88
4.1	Schematic of a digital microfluidic biochip that can perform DNA amplification [89][93]. . . . .	94
4.2	(a) Compact placement of a reservoir and a heater; (b) outer isothetic cover (OIC) that tightly encloses the forbidden region of $R_2$ ; optimal placement of a reservoir $R_2$ in the presence of a reservoir $R_1$ , a PD $P_1$ , and a heater $H$ . . . . .	102
4.3	(a) Sequencing graph for the dispensing and mixing of two droplets; (b) placement of the output port of reservoirs and the mixer; (c) an example of defect tolerance by droplet rerouting. . . . .	106
4.4	Pseudocode for layout design for PCR biochips. . . . .	108
4.5	Relationships between $i$ (i.e., the number of thermal cycles that have been carried out) and $P(G^c A_i)$ (i.e., the probability that “this droplet is an empty droplet”) derived using three statistical models of PCR procedure. . . . .	109
4.6	(a) Device placement obtained by the proposed algorithm. $R$ represents the output port of the reservoir, $P$ represents the PD, and $H$ represents the heater. All the reservoirs are treated as identical devices and all the PDs are treated as identical devices; (b) Reservoir allocation with the minimum droplet routing cost. $R_{1\sim 7}$ are reservoirs assigned to inputs $x_{1\sim 7}$ in Figure 4.7, $P_1$ and $P_2$ are PDs, and $H$ is the heater. The white squares correspond to electrodes. . . . .	111

4.7	Sequencing graph for a solution preparation procedure. The inputs of the mixing procedure are seven different kinds of samples/reagents and the final output is the droplet that has the mixing ratio of 2:3:5:7:11:13:87 [74]. These seven samples/reagents are loaded into reservoirs $R_{1\sim 7}$ on the PCR biochip. . . . .	111
4.8	(a) The result of device placement derived by the baseline algorithm. The output ports of reservoir 1 ~ 7, PD 1 ~ 2 and the heater are placed on the boundary of the layout one by one. $R_1$ and $R_2$ here represent the output ports of two reservoirs; (b) conflicts of droplet routing on the layout derived by the baseline algorithm. . . . .	113
4.9	(a) The positions of “catastrophic defects”. If the electrodes at these positions have defects, the biochip cannot be used any more; (b) non-catastrophic defect can be by-passed by adjusting the routing of droplets.	116
5.1	(a) Droplet transportation and dilution/mixing operations are scheduled in different phases; (b) start and end time of a D/M phase. . . .	123
5.2	A tunable frequency-divider controlled by the feedback from sensors.	123
5.3	Sequencing graph with tree structure (a) all edges are directed towards the root of the tree; and (b) all edges are directed away from the root; (c) scheduling results for mixing operations 1, 2, and 6; (d) module-placement for 1, 2 and 6; (e) storage units $S_1$ and $S_2$ inside the modules assigned for operations 1 and 2; (f) packaged macro-operations $M_{S_L}$ and $M_{S_R}$ ; (g) a feasible solution for module-placements of operation 1 ~ 5 on an $8 \times 8$ array. . . . .	124
5.4	(a) Partitioning of a sequencing graph; (b) the interdependency of macro-operation $M_T$ , operation $L$ and operation $R$ . . . . .	129
5.5	Assume two directed trees $T_x$ and $T_y$ have the relationships that $T_x < T_y$ and $T_x > T_y$ . . . . .	131
5.6	Pseudocode for operation-interdependency-aware synthesis. . . . .	133
5.7	Comparison between the number of droplets consumed in the biochips of [51][96] (droplet consumptions are the same for the methods of these two papers) and the proposed method. . . . .	142
5.8	The relationship between completion time of bioassays and $f_T$ on an $8 \times 8$ direct-addressing biochip. . . . .	146

6.1	(a) A central electrode and its non-diagonally adjacent electrodes comprising an electrode group; (b) an example of pin-actuation conflicts; (c) an example where two diagonally adjacent electrodes in the same CEG share one pin (Pin A); (d) an example where two non-adjacent electrodes in the same CEG share one pin (Pin A). . . . .	152
6.2	Six pin-assignment configurations that are analyzed in Cases (2.a)~(2.c) and Cases (3.a)~(3.e): (a) Case (2.a); (b) Case (2.b); (c) Case (2.c); (d) Case (3.a); (e) Case (3.c); and (f) Case (3.d). . . . .	154
6.3	Pseudocode for the construction of the pin-assignment configuration using a greedy algorithm. . . . .	162
6.4	(a) Coordinate locations for the electrodes; (b) pin-assignment for the electrodes; graphs corresponding to electrode (c) $E_{(1,2)}$ ; (d) $E_{(1,3)}$ ; (e) $E_{(2,3)}$ ; and (f) $E_{(3,3)}$ . . . . .	164
6.5	(a) The <i>union</i> of graphs $G_{(1,2)}$ and $G_{(1,3)}$ ; (b) the <i>union</i> of graphs $G_{(1,2)}$ and $G_{(3,3)}$ . The graphs $G_{(1,2)}$ , $G_{(1,3)}$ , and $G_{(3,3)}$ are shown in Figure 6.4(c), Figure 6.4(d), and Figure 6.4 (f), respectively. . . . .	166
6.6	(a) Three categories of electrodes and the graphs correspond to electrodes of (b) the first category (c) the second category (c) the third category. . . . .	169

# Acknowledgements

I thank Professor Chakrabarty for all his help and support in my research and career, and for taking the time to serve as the chair of my Ph.D. Committee. He is a model of how a great scientist and engineer should be: always enthusiastic, details-oriented, organized, and with amazingly diverse interests in a great range of fields. His door is always open and no matter how busy he was, he always had the patience to answer all my questions. Professor Chakrabarty gives me the opportunity, the resources, the means, the guidance, and the freedom to pursue my research directions.

I thank Professor Fair and Professor Ho for the inspiring discussions and valuable help on my thesis work. I would like to acknowledge my thesis committee Professor Derby and Professor Trivedi for their great support and service at my exams.

I thank Andrew C. Madison, Bang-Ning Hsu, Liji Chen, Kai Hu, Dr. Yan-You Lin, Dr. Yang Zhao from Duke University for valuable discussions and collaboration. A special thanks goes to my family for their encouragement and to my husband Yuchuan for all his loving support. Financial support received from the National Science Foundation is greatly appreciated.

## Introduction

Microfluidic biochips have emerged as powerful and reliable toolkits for biotechnology applications, such as chemical synthesis, the diagnosis of diseases, and the development of new drugs [1][2][3]. Nanoliter and picoliter volumes of biological samples can be manipulated on microfluidic devices under software control. Compared to conventional devices and analyzers, microfluidic devices offer many unique advantages. The low volume of samples and reagents manipulated on microfluidic devices can significantly reduce the costs associated with conducting experiments; the precise control of reactions on microfluidic devices can enhance the accuracy of the experiments; the time required for the chemical reactions to occur at the nanoliter scale can be greatly reduced due to the high surface-to-volume ratios. Based on the methods used to manipulate the liquid on the chip, microfluidic biochips are categorized as “flow-based chips” or “digital (droplet-based) chips” [4][5][6].

In continuous-flow chips, liquid flow on the biochip is achieved through micro-fabricated channels, pumps, and valves [7][8]. To overcome fluidic resistance, liquid in the channels is driven by external pressure sources. Such sources include external mechanical pumps and integrated, mechanical micropumps. The pressure required

for liquid flow also can be provided by combinations of capillary forces and electrokinetic mechanisms [7]. In recent years, the development of flow-based microfluidic devices has been accelerated by innovations in fabrication techniques, including the application of polydimethylsiloxane (PDMS) and the dense integration of active microvalves. From the early days, when flow-based biochips had simple topologies and only a few channels, commercial flow-based microfluidic devices today have large-scale networks of channels, and they can be used in various real-world applications. For example, a product from Fluidigm [9], a biotechnology company that focuses on flow-based microfluidic biochips, can perform a series of gene analyses, including enrichment for target DNA sequences, sample barcoding for multiplexed sequencing, and preparation of the sequencing library.

However, flow-based biochips have several inherent limitations and drawbacks. First, flow-based chips are difficult to integrate and scale down, as the scale of each component in the device may have a decisive impact on the performance of the entire system [5]. The second problem is that these chips cannot be reconfigured after they are fabricated because the channels are etched in the substrate [4]. Thus, the paths for liquid flow and all of the operations implemented by the chip are pre-determined, and no software-based differentiation is possible. The third problem is that these chips lack fault tolerance, hence the entire chip ceases to be functional if any channel or other on-chip element is defective [4].

Digital (droplet-based) microfluidic biochips have been proposed as an alternative to flow-based microfluidics [4][6]. On the droplet-based microfluidic platform, liquid droplets and all of the fluid-handling operations are manipulated using an array of discrete electrodes [1][3]. Since each droplet is analogous to “a bit of information” and operates under clock control, this device is referred to as a “digital microfluidic biochip” [3].

In digital microfluidic biochips, all molecular processes and biochemical reac-

tions are conducted using discrete droplets (or “packets of biochemical payload”) that have nanoliter/picoliter volumes, which allows a very significant reduction in reagent/sample volume and reaction time. Since microfluidic droplet platforms have the capability of conducting fast and efficient mixing inside droplets, high throughput can be achieved for experiments. The droplets on digital microfluidic biochips have no contact with any of the solid walls of the flow channels because they are surrounded by silicone oil and manipulated on the surface of the electrode array. Thus, as a benefit of this structure, the risk of cross contamination in experiments and the adsorption of reagents/samples by the walls of the channels are minimized. Therefore, the quality of the product droplet as well as the reliability of the biochip is improved.

Since discrete droplets are manipulated independently on the biochip, the droplet-based microfluidic biochip is especially suitable for researchers to closely monitor various reactions over time. For example, researchers have developed a droplet-based process for the identification and enumeration of foodborne pathogens [10]. In this process, each water-in-oil droplet acts as a microreactor for the encapsulation of the cell. By observing the metabolic activity of single bacteria cell that is confined by a picoliter-scale droplet, the detection and enumeration of bacteria can be performed quickly and precisely. The oil that surrounds each droplet acts as a carrier of droplets and a barrier against cross contamination. Compared with the conventional methods used to detect pathogens, in which researchers have to incubate the specimens for several hours or even days before the pathogens can be detected by conventional instruments, the method based on digital microfluidic biochips can significantly reduce detection time and improve the reliability of the measurement results.

Given all these advantages, digital microfluidics is now seeing increasing acceptance in biotechnology applications that require high-precision control of fluid flow during experiments [1][2][3]. The complexity of such systems and the integration level

of digital microfluidic biochips has increased markedly in the last few years. For example, a commercially-available droplet-based microfluidic system embeds more than 300,000 electrodes with integrated optical detectors [11]. The system is developed and optimized for single-cell gene expression, single nucleotide polymorphism (SNP) genotyping, protein expression, and the quantification of samples of DNA strands.

As the applications of digital microfluidic biochips grow, greater demands are likely to be placed on the quality of product droplets and the accuracy of fluid-handling operations. At the same time, the risk of errors during the execution of a bioassay is likely to increase due to the greater number of on-chip operations. For example, if a larger droplet that is to be split is not placed at the center of the splitter, unbalanced splitting may occur, and the resulting smaller droplets will have erroneous volumes.

Unlike the detection of defects involving the electrodes and the breakdown of the insulation layer, operational errors are difficult to predict or detect before the bioassay is conducted. For a biochip that does not have any hardware defects, operational errors are the main cause for the failure of bioassays. In order to improve the yield of bioassays and the automation of digital microfluidic biochips, it is necessary to develop an “intelligent” microfluidic system that has the capability of making on-line re-synthesis while a bioassay is being conducted.

Based on the existing hardware platform of biochips and emerging on-chip sensing techniques, the concept of a cyberphysical microfluidic biochip is proposed in this thesis work. In such a biochip, the control software and the hardware platform are tightly coupled. The status of the droplets is monitored in real-time by on-chip sensors. If an error is detected, the control software performs dynamic resynthesis to determine how to recover from the error. The dynamic re-synthesis procedure reschedules operations and reallocates on-chip resources to operations in order to minimize the completion time of the bioassay, while guaranteeing that there is no

conflict in resource sharing. By applying the control signal sequences derived by the re-synthesis procedure, the biochip discards the faulty droplets immediately to stop the propagation of the error. The operation that generated the faulty droplet(s) will be repeated. In this way, the biochip recovers from the effects of the operational error.

In order to minimize the size and cost of the system, a hardware-assisted error recovery method is also proposed in this thesis. Instead of the control software running on a computer, a finite-state-machine implemented on a field-programmable gate array (FPGA) is used to control the error-recovery procedure. Each state of the FSM represents one possible error that may occur on the biochip; for each of these errors, the corresponding sequence of error-recovery signals is stored in the memory of the FPGA before the bioassay is conducted. When an error occurs, the FSM transitions from one state to another, and the corresponding control signal is updated. Therefore, by using simple and inexpensive hardware (the FPGA), a portable, cyberphysical system can be implemented. This design is particularly convenient for handheld or portable devices that may emerge with future advances in technology.

In addition to errors in fluid-handling operations, another possible cause for the failure of a bioassay is the uncertainty in the completion time of fluid-handling operations. Due to the inherent randomness of biochemical reactions, the time required to complete each step of the bioassay can be viewed as a random variable. To address this issue, a new “operation-interdependence-aware” synthesis algorithm is proposed in this thesis. The start and stop time of each operation are determined by feedback from the on-chip sensor. Bioassays can therefore be carried out in a self-adaptive fashion on cyberphysical microfluidic biochips. With such a synthesis approach, the reliability and flexibility of the biochips are improved, and the applications of biochips can be extended beyond well-calibrated bioassays to the exploration of new

biochemical protocols.

To reduce the cost of fabricating biochips while maintaining flexibility with respect to potential applications, the concept of a general-purpose pin-limited biochip is introduced in this thesis. Using a graph model for pin-assignment, we have developed the theoretical basis and a heuristic algorithm to generate optimized pin-assignment configurations. The associated scheduling algorithm for on-chip biochemistry synthesis is also presented. A complete design flow for pin-limited cyberphysical microfluidic biochips is presented on the basis of these results.

Another design problem addressed in this thesis is a layout-design algorithm that can minimize the interference between the devices on a biochip. A probabilistic model for the polymerase chain reaction (PCR) process is considered; based on the model, the control software can make on-line decisions regarding the number of thermal cycles that must be performed in the PCR procedure. Therefore, the duration of the PCR can be controlled precisely.

The rest of this chapter is organized as follows. Section 1.1 presents an overview of digital microfluidics. Section 1.2 introduces the design automation aspects of digital microfluidic biochips. Section 1.3 presents a chapter-by-chapter outline for this thesis.

## 1.1 Overview of digital microfluidics

In this section, we present an overview of digital microfluidics, including the hardware platform and sensing techniques.

### 1.1.1 *Hardware platform*

A digital microfluidic biochip consists of a two-dimensional electrode array and on-chip reservoirs [13]. By utilizing the effect of electrowetting, nanoliter droplets containing biological/chemical samples and reagents can be manipulated on the chip

FIGURE 1.1: Schematic cross-section of a unit cell on the microfluidic biochip [12].

without curved channels or external pressure sources [4][12].

Figure 1.1 [12] shows the structure of a unit cell on a digital microfluidic biochip. The upper plate is a large electrode which covers all cells on the array and serves as the ground electrode for all unit cells [12][13]. When the biochip is used, the upper plate is applied a common voltage, thus all the unit cells in the array have the same voltage on their upper electrodes [12][13]. The lower plate of the unit cell consists of an array of discrete control electrodes. During chip operation, the unit cells in the array may have different voltages on their lower electrodes. The movements of droplets are determined by signals applied on the discrete electrodes. In the literature on microfluidic biochips, the term “control voltages applied to electrodes” usually refers to the voltages applied to the lower electrodes of the unit cells on the chip.

As shown in Figure 1.1 [12], droplets manipulated by the digital microfluidic biochip are confined between the upper and lower electrodes [12]. To move a droplet, a high voltage should be applied to a unit cell adjacent to the droplet, and at the same time, a low voltage must be applied to the cell under the droplet [12]. The voltages applied to the electrodes can influence the surface characteristics of the hydrophobic coating on the lower electrodes. In this way, the different voltages applied to the electrodes result in different levels of interfacial tension on the surface of the biochip [12]. Due to this effect, the droplet is moved from the low-voltage electrode to the high-voltage electrode[12]. This is the basic operating principle of

FIGURE 1.2: Several generations of fabricated and packaged digital microfluidic biochips [14].

digital microfluidic biochips. All microfluidic functions, such as droplet merging, splitting, mixing, and dispensing can be reduced to a set of basic operations [12]. Concurrent manipulation of multiple discrete droplets can be coordinated by control software and by voltages applied to the electrodes, without the use of mechanical devices, such as tubes, pumps, and valves [4].

Figure 1.2 [14] shows several generations of fabricated and packaged digital microfluidic biochips. The electrodes in these devices are fabricated on printed circuit boards (PCBs). Similar biochips have been fabricated on glass and silicon, and demonstrated for a wide variety of biomedical assays, including on-chip chemistry for DNA sequencing [1], multiplexed real-time polymerase chain reaction [15], protein crystallization for drug discovery [16], and cytotoxicity assays [17].

The process of fabricating microfluidic biochips on silicon wafers is described in [18]. In this process, the wafer is coated with a layer of  $\text{SiO}_2$ , which is used as the bulk insulation layer. Figure 1.3(a) shows electrodes fabricated on a silicon wafer. Two metal layers are deposited to form the interconnects. A cross-sectional view of a silicon-based biochip is shown in Figure 1.3(b) [18].

The silicon-based microfluidic biochip in [18] can be used to generate and manipulate droplets that have volumes of 300 pL, and the actuation voltages required for dispensing and transporting a droplet are 11.4 V and 7.2 V, respectively.

FIGURE 1.3: (a) Electrodes of a silicon-based biochip [18]; (b) side view [18].

### 1.1.2 Sensing systems

The development of integrated biomedical analysis systems requires miniaturized, integrated, and robust sensing systems [19]. Sensing systems on biochips can be divided into three categories based on their working principle, i.e., droplet visualization monitoring system, on-chip capacitive sensor, and on-chip photodetector. More details about each of these systems are provided below.

#### **Droplet visualization system**

Cameras can be used to record the movements of multiple droplets on the biochip simultaneously. The setup of the droplet visualization system is shown in Figure 1.4 [20]. By analyzing the images captured by the cameras, droplet dispensing, transportation, and mixing can be monitored. An example is shown in Figure 1.5 [20].

FIGURE 1.4: Setup of droplet visualization system: two CCD cameras are fixed on the biochip platform to get top view and side view of droplets [20].

One KCl droplet and one fluorescein droplet are mixed by repeating the splitting and merging operations. The time-lapsed images obtained from the top view show the procedure by which the fluorescein is diffused inside the droplet. Finally, the fluorescein will be distributed homogeneously inside the merged droplet.

When the bioassay is being conducted, the control software compares the images of the droplets in each intermediate step with the reference image of a fully-mixed droplet. In this way, the control software can determine the extent to which the mixing operation has approached completion [21]. In Chapter 2, we will show that the droplet visualization system also can be used for automatic tracking of droplets on biochips and for error detection.

### Capacitive sensors

The upper and lower electrodes in each unit cell of the microfluidic biochip form a parallel-plate capacitor. The capacitance associated with the pair of electrodes can be measured by the resistor-capacitor (RC) circuit shown in Figure 1.6 [22]. Since

FIGURE 1.5: Mixing of fluorescein and KCl droplets [21].

FIGURE 1.6: Circuit for capacitive sensing of biochip [22].

the droplet's permittivity is different from that of the filler medium of the biochip, the capacitance of a unit cell will change when a droplet is moved to it. In this way, the movement of a droplet can be monitored.

Capacitive sensors can also be used to detect whether the droplet is contaminated by particles. As shown in Figure 1.7 [23], a droplet may be contaminated by dust particles or by another small droplet that contains a different reagent. A contaminating particle changes the capacitance of the droplet. This difference can be detected

FIGURE 1.7: A droplet with particle contamination [23].

by capacitive sensors. The minimum radius of a contaminating particle that can be detected by the capacitive sensor has been derived using theoretical calculations in [23].

By using the experimental setup shown in Figure 1.8 [24], the relationship between the volume of droplet and the capacitance of a unit cell can be measured. During the measurement procedure, liquid is injected from the top of an electrode of the digital microfluidic biochip via a hole using a syringe pump. The flow rate of injected liquid is set as a constant, hence the volume of the droplet can be calculated based on the pumping time. By repeating the measurement procedures, the relationship about the volume of the droplet and the capacitance of electrode pair can be determined. Using this relationship and calibrated curve, during bioassay execution, the precise location and volume of each droplet can be estimated based on the feedback from capacitive sensors.

### Photodetectors and optical sensing

Photodetectors can be used for sensing because they convert the intensity of fluorescence of droplet on chip into electrical signals [25][26][27]. These electrical signals can subsequently be used as the feedback to the control software of the biochip.

FIGURE 1.8: Experimental setup for measuring the relationship between the volume of droplet and the capacitance of the unit cell [24].

## 1.2 Computer-aided design and optimization

In recent years, design automation methods for digital microfluidics have received much attention [28][29][30][31]. In order to map an abstract representation of the desired bioassay protocol, e.g., a sequencing graph, into a design implementation in terms of fluidic handling operations, a unified synthesis tool for digital microfluidic-based biochips is described in [32]. The inputs of the synthesis tool are the bioassay protocol, constraints on the available resources on the biochip, and a library of module that can implement fluidic operations; the outputs are a mapping of assay operation to on-chip resources and a schedule for the fluidic steps.

The synthesis procedure proposed in [32] includes architectural-level synthesis and geometry-level synthesis. Architectural-level synthesis can be viewed as the problem of scheduling fluidic handling operations and binding them to a given number of resources. On the other hand, geometry-level synthesis addresses the placement of resources to satisfy area constraints. In order to get an optimized solution, the parallel recombinative simulated annealing (PRSA) algorithm forms the core of the synthesis procedure in [32].

The PRSA-based algorithm for digital microfluidic biochips includes two parts: (1) the random generation of a large number of feasible synthesis configurations for the microfluidic biochips that satisfy all the resource and utilization constraints and dependency between operations; (2) the use of the PRSA algorithm to select an optimized synthesis configuration from these candidates. In this way, the tool can derive, from a high-level specification, synthesis results that satisfy all the constraints related to on-chip resources and minimize a given cost function under resource constraints. Figure 1.9 illustrates the high-level synthesis flow.

FIGURE 1.9: The high-level synthesis procedure [32].

A drawback of the synthesis procedure of [32] is that it does not consider droplet routing. In some cases, the droplet transportation paths may all be blocked by other modules on the biochip, and no feasible routing solution can be derived. To solve this problem, the authors of [33] propose an improved PRSA-based synthesis algorithm that considers the time of droplet transportation as a criterion during design

optimization. This approach can improve the routability of the synthesis results, even though it does not generate routing paths of droplets nor does it guarantee the existence of a routing solution.

Several algorithms for determining optimized droplet routing paths are proposed in [28][31][34][35]. In [28], droplet routing is modeled as a motion-planning problem for multiple robots, and the  $A^*$  search technique is used to determine the shortest routing path.

The electrical I/O interface for digital microfluidics poses challenges. If each electrode is controlled by an independent pin and each pin has an input pad fabricated on the chip, the area required for the biochip will be extremely large. Hence, the fabrication cost will be high. In order to reduce the number of control pins and to control the digital microfluidic array without significantly affecting concurrent droplet operations, several design optimization techniques have been proposed and analyzed in the literature [34; 36; 37; 38]. These methods reduce the number of pins in two different ways. One way is to reduce the number of pins by designing the biochip with some special structures. For example, in the n-bus-phase scheme, every  $n^{th}$  electrode is connected to the same control pin [36]. Another example is the cross-referencing biochip proposed in [37]. For the cross-referencing (row-column) scheme, the upper electrodes of all of the unit cells in the same row are connected to the same control pin, and the lower electrodes of all of the unit cells in the same column are connected to the same control pin. A different approach for reducing the number of control pins is to exploit knowledge about the target bioassay and divide the set of electrodes into groups based on the control signals that are applied on them. Electrodes that have compatible signal sequences are connected to the same pin [34; 38].

The above discussion has highlighted the design flow for digital microfluidic biochips. This design flow includes four stages, namely 1) high-level synthesis, 2)

FIGURE 1.10: Comparison between the conventional design flow and the chip-level biochip design flow [39].

droplet routing, 3) the derivation of pin-assignment configuration, and 4) the derivation of the wire-routing solution. Figure 1.10(a) illustrates the overall design flow [39]. “Fluidic-level synthesis” (which includes Stages 1 and 2), and “physical design” (which includes Stages 3 and 4), are optimized separately.

An integrated design flow of a biochip, which aims at filling the gap between fluidic-level synthesis and chip-level design, is proposed in [39]. The conventional and proposed design flows in [39] are compared in Figure 1.10. In the synthesis stage, the concepts of “synchronous reaction” and “device count aware scheduling” are introduced. The reusability of modules can be improved and the number of control pins required can be minimized [39]. Next, the modules that correspond to these scheduled operations are placed on the biochip. Based on the device-count-aware scheduling algorithm, the number of modules and the shapes of the modules are determined. The placement of modules and the assignment of resources are determined to minimize the transportation distances for the droplets. Electrodes are classified

into three categories, i.e., bus, branch and device electrodes. The pin-assignment methods and wire routing strategies for these three categories are different. For example, the same types of devices that are used to implement synchronous operations will share the same group of control pins. In this way, co-optimization for the synthesis result of the bioassay, pin assignment configuration of the biochip, and metal wire routing solution is achieved.

For biomedical applications such as clinical diagnostics, it is necessary to ensure the accuracy of on-chip fluidic operations. The accuracy of fluid-handling operations can be monitored by examining parameters such as the volume and concentration of product droplets. If an error occurs during the execution of the bioassay, for instance, the volume of an intermediate product droplet exceeds the normal value, the assay outcomes can be incorrect and the whole experiment needs to be re-executed. Therefore, it is important to detect such errors as early as possible and re-execute the corresponding fluid-handling operations to obtain correct bioassay outcomes.

In [40], the authors proposed a conceptual mechanism to monitor the intermediate products of bioassay and implement error-recovery operations to minimize the influence of error operations. A sequence of checkpoints is inserted into the initial protocol of the bioassay. At these checkpoints, sensors are used to check the quality of intermediate droplets. If the droplets fail to meet the quality requirements, the detector sends an interrupt to the control software, and some fluid-handling operations are re-executed. In this way, error recovery can be carried out automatically.

### 1.3 Thesis outline

This thesis research addresses a number of optimization problems related to cyber-physical microfluidic biochips. The reminder of the thesis is organized as follows.

Chapter 2 presents a transformative cyberphysical approach towards achieving closed-loop and sensor feedback-driven biochip operation under the program control.

Section 2.1 presents the motivation for developing a “physical-aware” system reconfiguration technique that uses sensor data at intermediate checkpoints to dynamically reconfigure the biochip. Section 2.2 develops an algorithm for the measurement and tracking of droplets based on real-time imaging data from a charge-coupled device (CCD) camera. Section 2.3 introduces a reliability-driven error recovery strategy. Section 2.4 presents the parallel recombinative simulated annealing (PRSA)-based and greedy algorithms for reliability-driven synthesis. In Section 2.5, simulation results for three representative bioassays are discussed. Finally, conclusions are drawn in Section 2.6.

A hardware-assisted error-recovery method that relies on an error dictionary for rapid error recovery is presented in Chapter 3. The research motivation for the hardware-assisted cyberphysical biochip is introduced in Section 3.1. The proposed algorithm for creation of the error dictionary is presented in Section 3.2. Section 3.3 introduces the generation of actuation matrices corresponding to synthesis solutions in the error dictionary. Section 3.4 describes the procedures for compaction of the error dictionary. The implementation of dictionary-based error recovery on FPGA is introduced in Section 3.5. A fault simulation method with consideration of parameter variation in the fabrication process is discussed in Section 3.6. Simulation results are shown in Section 3.7, and conclusions are presented in Section 3.8.

Chapter 4 presents the optimization algorithms for PCR on a cyberphysical digital microfluidic biochip. The working principle of the PCR biochip is introduced in Section 4.1. Section 4.2 describes the statistical model for the amplification of DNA strands and the on-line decision making method during an actual experiment. Section 4.3 presents the layout design algorithm with the consideration of device interferences. It also describes an application-specific reservoir allocation method. Simulation results for three widely used bioassays are presented in Section 4.4. Section 4.5 concludes the chapter.

Chapter 5 describes the synthesis algorithm for bioassays under completion-time uncertainties in fluidic operations. Section 5.1 discusses the drawbacks of previous uncertainty-oblivious methods of biochip design. Section 5.2 presents the design of microfluidic biochips with multiple clock frequencies. Section 5.3 introduces the framework of operation-dependency-aware synthesis. Based on results derived from the proposed synthesis algorithm, integrated on-line decision-making for droplet transportation path is presented in Section 5.4. Simulation results are presented in Section 5.5. Section 5.6 concludes the chapter.

The design procedure for a general-purpose microfluidic biochip is presented in Chapter 6. Section 6.1 describes previously published pin-assignment algorithms and their limitations. Section 6.2 presents an analysis of pin-actuation conflicts, and derives the necessary and sufficient conditions for control-pin sharing to ensure high flexibility in the concurrent movement of two droplets. Section 6.3 introduces an integer linear programming model for designing a pin-assignment with the smallest number of pins. Section 6.4 presents a graph-theoretic method to formulate an acceptance test for a pin-assignment configuration and a lower bound on the number of pins. A heuristic algorithm that generates a pin-assignment configuration for biochips is proposed in Section 6.4. Extension of the study from  $1 \times$  volume droplets to  $2 \times$  and even larger droplets is presented in Section 6.5. Section 6.6 presents the scheduling algorithm that can be applied to biochips with pin-constraints. Simulation results for commercial biochips and experimental prototypes are discussed in Section 6.7. Finally, conclusions are drawn in Section 6.8.

Based on the work discussed in Chapters 2-4 and Chapter 6, the concept of pin-limited cyberphysical microfluidic biochip is proposed in Chapter 7. The structure and layout design of two-metal-layer biochips are introduced in Section 7.1. In Section 7.2 the wire-routing solution for general-purpose pin-limited biochips is proposed. The specific design flow for pin-limited cyberphysical biochips is discussed in

Section 7.3. Results for several experimental bioassays are discussed in Section 7.4. Finally, conclusions are drawn in Section 7.5.

Finally, Chapter 8 summarizes the contributions of the thesis and identifies directions for future work.

## Error Recovery in Cyberphysical Biochips

In this chapter, by exploiting recent advances in the integration of sensing system in a digital microfluidics biochip, we present a “physical-aware” system reconfiguration technique that uses sensor data at intermediate checkpoints to dynamically reconfigure the biochip. A cyberphysical re-synthesis technique is used to recompute electrode-actuation sequences, thereby deriving new schedules, module placement, and droplet routing pathways, with minimum impact on the time-to-response.

The key contributions of this chapter are as follows:

- A charge-coupled device (CCD)-based sensing system for digital microfluidic biochips (Section 2.2).
- An algorithm for the measurement and tracking of droplets based on real-time imaging data from a CCD camera (Section 2.2).
- A reliability-driven error recovery strategy (Section 2.3).
- Parallel recombinative simulated annealing (PRSA)-based and greedy algorithms for reliability-driven synthesis (Section 2.4).

- Simulation results for three representative bioassays (Section 2.5).

## 2.1 Motivation and related prior work

The ease of reconfigurability and software-based control in digital microfluidics has motivated research on various aspects of automated chip design and chip application. A number of techniques have been published for architectural-level synthesis [32], module placement, and droplet routing [31][41][42]. However, these techniques ignore domain-specific constraints or practical realities that arise from attempting to carry out biochemical reactions and microfluidic operations on an electronic chip. Due to the randomness and complex component interactions that are ubiquitous in biological/chemical processes, predictive modeling and accuracy control are difficult [43; 44].

In addition to manufacturing defects and imperfections, faults may also arise during bioassay execution. For example, excessive actuation voltage applied to an electrode may lead to breakdown of electrodes and charge trapping, and DNA fouling may lead to malfunction of multiple electrodes in the biochip [45][46][47]. These faults are hard to detect *a priori*, but they occur often during bioassays [47]. Yet, despite such inherent variability, many biomedical experiments, such as drug development and clinical diagnostics, require fluid-handling operations that are highly accurate and precise. Each step in the protocol of a biochemical experiment has an “acceptance range” for the volume and concentration of droplets. For example, in the preparation of samples of plasmid DNA, the pH of the solution must be less than 8.0 to avoid a significant reduction in the efficiency of the lysozyme [48]. If an unexpected error occurs during the experiment and the requirements of the bioassay protocol are violated, the outcome of the entire experiment will be incorrect. When this occurs, all the steps of the experiment must be repeated to correct the error [40][49]. Repetition of experiments leads to wastage of expensive reagents and

hard-to-obtain samples.

The repetitive execution of on-chip laboratory experiments leads to the following problems: (i) wastage of samples that are difficult to obtain or prepare, and the wastage of expensive reagents; (ii) an increase in the time-to-result for a bioassay, which is detrimental to real-time detection and rapid response. Therefore, it is necessary to develop techniques for monitoring assay outcomes at intermediate stages and design an efficient error-recovery mechanism.

Error recovery in digital microfluidics has received relatively little attention in the literature. The only reported work is [40], which proposed intermediate stage monitoring and rollback error-recovery for a microfluidic biochip. The key idea in this work is to use sensing system to verify the correctness of immediate product droplets at various steps in the on-chip experiment. Sensors has been integrated with digital microfluidics to evaluate the concentration and volume of product droplets [1]. In the recent approach described in [40], error recovery is carried out as follows. During bioassay execution, intermediate product droplets are sent to sensors. When an error is detected at a sensor, i.e., the volume or concentration of the droplet is below or above the acceptable calibrated range, the corresponding droplet is discarded. The operations whose outputs fail to meet the quality requirements based on sensor calibration are re-executed to generate a new product droplet to replace the unqualified droplet.

Figure 2.1 shows an example of rollback error-recovery. The initial sequencing graph of a bioassay is shown in Figure 2.1(a). Here we assume that the outputs of each dispensing, mixing and splitting operation are evaluated by a sensor. When an error occurs at operation 9, the system will re-execute the corresponding dispensing and mixing operations. The new sequencing graph for error recovery is shown in Figure 2.1(b). Operations 12, 13, and 14 are added for error recovery.

In the absence of “physical-aware” control software, the error recovery method

FIGURE 2.1: (a) Initial sequencing graph; (b) operations 12, 13, and 14 are added for error recovery.

in [40] suffers from following drawbacks:

1. The first drawback is the over-simplification of fault detection and the associated assumptions. Using a uniform “expected value” for the calibration of each detection operation is not practical. Note that at various stages during bioassay execution, the concentration of intermediate product droplets vary in a dynamic manner, hence the calibration also needs to be repeated and carried out dynamically.
2. In [40], all recovery operations are carried out in a stand-alone manner. When an error is detected, all other ongoing bioassay-related fluidic operations are interrupted. The potential long waiting times introduced by recovery operations can lead to sample degradation and erroneous assay outcomes [50]. Some operations, such as colorimetric enzyme-kinetic reactions, require precise durations as specified by the reaction protocol, and they cannot be extended without introducing unpredictability in the experiment outcome [26].
3. The error recovery approach in [40] cannot handle situations when multiple

FIGURE 2.2: The schematic of the cyberphysical digital microfluidic system.

errors occur during a bioassay. For example, it assumes that all error recovery operations will be executed successfully and it does not consider the likelihood that errors can also occur during recovery.

4. The error recovery strategy in [40] does not consider reliability issues. Errors such as the generation of droplets with abnormal volumes are usually caused by the accumulation of charge on the surface of certain electrodes [45][46]. If the use of such electrodes is continued, it is likely that they will introduce more errors [45][46]. Thus, in order to ensure the reliability of biochips, we must minimize the utilization of these electrodes.

To overcome the above drawbacks, we take a transformative “cyberphysical” approach towards achieving closed-loop and sensor feedback-driven biochip operation under program control. By exploiting recent advances in the integration of sensing system in a digital microfluidics biochip [27], we present a “physical-aware” system reconfiguration technique that uses sensor data at intermediate checkpoints to dynamically reconfigure the biochip [51].

## 2.2 Overview of cyberphysical biochips

In this section, we introduce propose cyberphysical system on microfluidic biochips and introduce each component of the system. With the availability of sensing system for biochips, “physical-aware” control software becomes feasible. By “physical-

FIGURE 2.3: Illustration of a digital microfluidics-based image processing system [52].

aware”, we refer to the fact that the software can receive information about the outcome (error-free/erroneous) of fluid-handling operations based on feedback from the sensing system. Depending on sensor feedback, the control software can appropriately reconfigure the microfluidic biochip. In this way, the various steps in the bioassay are executed based upon real-time sensing of intermediate results.

Figure 2.2 depicts each component of a cyberphysical system on the microfluidic platform. The control software sends a control signal to the microfluidic biochip, and the on-chip sensing system monitors the outcomes of fluidic operations. The outcomes are compared with the “expected values”, i.e., the pre-determined thresholds. If the results of the comparison indicate that an error has occurred, the control software receives a “repeat request”, and the corresponding operation in which the error occurred can be executed again, thereby correcting the error.

### 2.2.1 Sensing systems

As described in Chapter 1, CCD cameras can be used in experiments to view the top sides of droplets simultaneously. An example of the CCD monitoring system is shown in Figure 2.3.

Based on images captured by the CCD camera, droplets can be automatically located by the control software. The procedure of automatically searching for droplets can be described as a “template matching” problem. Here a pattern can be represented as the image of a “typical” droplet. During the matching process, we move the template image to all possible positions in the image of the entire array and crop a sub-image that has the same size as the template image. Then the control software computes the correlation index, which indicates the similarity between the template and the “cropped image”. This process is shown in Figure 2.4(a) and the correlation factor is calculated on a pixel-by-pixel basis.

In the control software, all images are stored in grayscale form, which can be encoded as matrices or vectors. Suppose the template image is represented in a 1-D array:  $\vec{x} = (x_1, x_2, \dots, x_N)$ . Here  $x_i$  represents the gray level of a pixel and  $N$  is the total number of pixels in the template image. Similarly, the cropped sub-image to be compared with the template image can be written as  $\vec{y} = (y_1, y_2, \dots, y_N)$ . Thus the correlation factor between these two images is defined as:

$$cor = \frac{\sum_{i=1}^N (x_i - \bar{x}) \cdot (y_i - \bar{y})}{\sqrt{\sum_{i=1}^N (x_i - \bar{x})^2 \cdot \sum_{i=1}^N (y_i - \bar{y})^2}},$$

where  $\bar{x}$  and  $\bar{y}$  are the average gray level in the template image and cropped sub-image, respectively. The range of correlation factor  $cor$  is a real number between  $-1$  and  $+1$ . According to the definition of correlation, a larger value represents a stronger relationship between two images.

After deriving the correlation factors for all possible positions in the image for the complete biochip, we obtain the correlation map between the template and the original input image. Suppose there are  $\kappa$  droplets on the biochip. By searching for the largest  $\kappa$  correlation factors in the correlation map, the locations of droplets can be determined. An example is shown in Figure 2.4(b) and (c) [53]. Part (b)

FIGURE 2.4: (a) The matching process moves the template image to all possible positions in a larger source image and computes a numerical index that indicates how well the template matches the sub-image in that position; (b) the image of the whole biochip [53] and the pattern we selected; (c) the correlation map between image of the whole array and the pattern. The positions of droplets can be determined by finding  $\kappa$  maximum elements ( $\kappa$  is the number of droplets on the chip) in the correlation map.

shows the original input image of the whole chip and the pattern image, and (c) is the correlation map, where the best matching locations, i.e. the coordinations of droplets derived by the control software are (77, 107), (77, 147) and (76, 208). Thus the control software automatically locates the droplets, and it can further analyze the sizes and colors of droplets according to the image. In this manner, the volumes and concentrations of droplets can be acquired after processing the image taken by the CCD camera.

Instead of searching for droplets in the complete image, we use imaging to check whether the droplets have been moved to the expected positions. This is implemented using the following steps:

First, we do some calibration before the experiment. We choose a large number of sub-images with (or without) droplets, and calculate their correlation with the template. Based on this calculation, we find an appropriate threshold for the correlation index ( $C_{th}$ ): if the correlation is larger than  $C_{th}$ , we conclude that there is a droplet in the cropped sub-image; otherwise, there is no droplet in the sub-image. When the bioassay is running, we only need to crop the sub-images near the expected positions of droplets, and calculate their corresponding correlation indices to determine the absence/presence of droplets.

The advantages of the CCD camera-based sensing system are: (i) the detection of errors immediately after they occur and (ii) the identification of the precise locations of the errors. A disadvantage of this system is that extra instruments, such as CCD cameras, are required to observe the cyberphysical system.

### *2.2.2 “Physical-aware” software*

The availability of on-chip sensors provides digital microfluidic biochips with the capability of using sensor data at intermediate checkpoints to detect errors, thereby minimizing the impact of errors that occur during bioassay execution. The work in [40] proposed intermediate stage monitoring and rollback error-recovery for a microfluidic biochip. The key idea in this work is using the sensing system on-chip to verify the correctness of output droplets at various steps in the on-chip experiment. In this approach, error recovery is carried out as follows. When an error is detected at a checkpoint, operations whose outputs failed to meet the quality requirements based on sensor calibration are re-executed to recover from the error. Additional intermediate product droplets must be stored in specially designated locations of the chips to facilitate recovery. Additional droplets of samples and reagents must also be dispensed from reservoirs for error recovery. The details of the strategy for reliability-driven error recovery are presented in Section 2.3, and the algorithm for dynamic re-synthesis of error recovery is described in Section 2.4.

FIGURE 2.5: The schematic of the cyberphysical digital microfluidic system. Software running on the computer and the biochip are coupled by a field-programmable gate array (or a single-board microcontroller) and peripheral circuit.

### 2.2.3 Interfaces between biochip and control software

We next describe the cyberphysical coupling between the control software and the hardware of the microfluidic platform. There are two interfaces needed for cyberphysical coupling. The first interface converts the output signals from the sensing system to the inputs of the desktop computer that the control software can interpret. The second interface converts the output data generated by the control software to voltage signals that can be directly applied to the electrodes of the biochip.

A schematic representation of the cyberphysical system is shown in Figure 2.5. The system consists of a computer, a single-board microcontroller, a peripheral circuit, and the biochip. During the execution of a bioassay, the software running on the computer sends control signals to the biochip. At the same time, the software receives feedback from the sensing system on the biochip through the single-board microcontroller. The control software recomputes the schedule of fluidic operations, module placement, and droplet pathways depending on sensor feedback. This process is referred to as reconfiguration and the key idea is to use an on-chip sensing system for concurrent monitoring of experiments. When an error is detected by on-chip sensors, error propagation is prevented by the immediate discarding of the abnormal droplet. The biochip implements error-recovery operations in subsequent

cycles.

The closed-loop integration in cyberphysical microfluidics can also be used to control the completion time of bioassays. For example, in the measurement of glucose in blood, serum samples need to be well-mixed with an enzymatic reagent [54]. During the mixing procedure, the status of the droplet is monitored by an image sensor. The extent to which mixing has been completed can be quantified by analyzing images for the droplet. Therefore, the control software will force the biochip to continue mixing until the feedback information shows that the droplets are sufficiently well-mixed. Hence the mixing operation can be precisely controlled without knowing the precise mixer execution time in advance, and the on-chip measurement results for glucose concentration can be as precise as the results derived by a traditional bench-top analyzer used by a laboratory technician [54].

## 2.3 Reliability-driven error recovery

### 2.3.1 *Error recovery strategies*

In this subsection, we formulate the principles underlying error recovery. For the given bioassay protocol, we use the sensing system on-chip to evaluate the quality of output droplets of each dispensing, mixing, dilution and splitting operation. According to the data provided by [1], the response time of on-chip sensors are in the scale of picoseconds or nanoseconds. Thus the time cost for adding detection operations is negligible.

For a microfluidic biochip, fluid-handling operations can be divided into two categories: reversible and nonreversible operations. Reversible operations include dispensing and splitting operations; nonreversible operations include mixing and dilution operations. For errors that occur at reversible operations, their recovery processes are relative simple. In a splitting operation, if two droplets with unbalanced volumes are generated, then the biochip will first merge the two abnormal droplets to a larger one and then split the larger droplet again. For errors that occur at a dispensing operation, the chip can send the abnormal droplet back to the corresponding reservoir and dispense another droplet. Thus for errors that occur at

FIGURE 2.6: (a) An example of a sequencing graph corresponding to a bioassay protocol; (b) the layout of a biochip with reserved area for error recovery.

reversible operations, the time cost for recovery is small and no additional droplets need to be consumed.

The error recovery process for nonreversible operations is more involved. To implement the corresponding nonreversible operations to correct the error, we also need input droplets from operations whose outputs feed the inputs of the failed operation. Thus we may need to re-execute all the predecessors of the erroneous operation. For instance, if an error occurs at operation 7 in Figure 2.6(a), operations 1, 2, 3, 4, 5, and 6 may need to be re-executed. Thus the time cost for executing error recovery operations can be extremely high. To reduce the incidence of the worst case, the following strategies are taken in our approach:

- For a splitting operation, if only one of its output droplets is used as the input for the immediate successors, we store the other (redundant) droplet as a backup for possible error recovery at a subsequent stage. For example, operation 7 in Figure 2.6(a) is a splitting operation and it generates two output droplets. Only one of these two droplets is used as the input of operation 9. (Note here each circle in the sequencing graph stands for a fluid-handling operation. The unused droplets are not shown in the sequencing graph.) If an error occurs at operation 9, the redundant droplet will be used as an input for re-execution.

- All dispensing operations are scheduled for execution as early as possible and their output droplets are stored on the biochip. We also dispense some droplets as backup for possible error recovery operations. When the bioassay is completed, those

unused backup droplets are sent back to the corresponding reservoirs.

Thus, when an error occurs at a nonreversible operation, the control software first checks whether the inputs of this operation can be provided by backup droplets stored on chip. If the answer is yes, then the time cost for this operation can be reduced. Otherwise, more operations will be executed during error recovery. Based on the above discussion, the operations in the sequencing graph can be divided into three categories according to the number of operations and droplet consumptions in their error recovery processes, as shown in Figure 2.6(a).

The above operations can be formally categorized as follows:

Category I: This is the set of all reversible operations. They can be simply re-executed when an error occurs.

Category II: This is the set of nonreversible operations for which immediate predecessors can provide backup droplets.

Category III: This corresponds to the set of nonreversible operations for which their immediate predecessors cannot provide backup droplets.

In a given sequencing graph, each node represents an operation. We define the number of input droplets as the in-number of an operation, and the number of output droplets as the out-number of an operation. As described below, any operation  $opt_k$  can be categorized based on its in-number and out-number values:

- If in-number of  $opt_k$  is equal to zero, then  $opt_k$  is a dispensing operation. Thus we have:  $opt_k \in \text{Category I}$ .
- If in-number of  $opt_k$  is equal to one and the out-number of  $opt_k$  is equal to two, then  $opt_k$  is a splitting operation. Thus we have:  $opt_k \in \text{Category I}$ .
- Suppose  $opt_j$  is an immediate predecessor of  $opt_k$ . Then the number of backup droplets at the output of  $opt_j$  can be calculated as:  $B_{opt_j} = ON_j - MN_j$ , where  $ON_j$  is out-number of  $opt_j$ , and  $MN_j$  is the number of immediate successors of  $opt_j$ . If the numbers of backup droplets for  $opt_k$ 's immediate predecessors are all non-zero, then we have:  $opt_k \in \text{Category II}$ ; otherwise,  $opt_k \in \text{Category III}$ .

For an operation  $opt_i$ , the set of its error recovery operations,  $\mathcal{R}_i$ , can be derived according to the categorization result for  $opt_i$ . Operations in Category I and II can be simply re-executed when an error occurs because their input droplets are stored on chip. However, for operations in Category III, their inputs come from the outputs of predecessor operations and we do not have backup for these droplets. Thus if an error occurs in an operation of Category III, we not only need to re-execute the operation itself but also need to backtrace to its predecessors. Suppose the error operations is  $opt_e$  and its immediate predecessors are operation  $opt_{p_1}$  and  $opt_{p_2}$ . If these immediate predecessors are operations in Category I or Category II, we can first re-execute  $opt_{p_1}$ ,  $opt_{p_2}$  and then  $opt_e$  for error recovery, thus  $\mathcal{R}_i = \{opt_{p_1}, opt_{p_2}, opt_e\}$ . If the immediate predecessors  $opt_{p_1}$  and  $opt_{p_2}$  are neither in Category I nor Category II, we have to continue enlarging  $\mathcal{R}_i$  by adding the immediate predecessors of  $opt_{p_1}$  and  $opt_{p_2}$  into  $\mathcal{R}_i$ . This backtracing and enlargement procedure needs to be repeated until we reach predecessor operations that can provide backup droplets to feed the inputs of operations in the set of error operations.

The above procedure of backtracing and enlargement of the set  $\mathcal{R}_i$  can be described as follows. First, we define the mapping  $pred(opt_i)$  to be a mapping from  $opt_i$  to the set of immediate predecessors of  $opt_i$  in the sequencing graph.

For a set of operations  $\mathcal{O} = \{opt_{o_1}, opt_{o_2}, \dots, opt_{o_k}\}$ , we define the operator  $\mathcal{P}_r$  as:

$$\mathcal{P}_r : \mathcal{O} \rightarrow \bigcup_{i=o_1, o_2, \dots, o_k} \{opt_i, opt_j | opt_j \in pred(opt_i), \forall j\}$$

where  $\mathcal{P}_r$  is a backtracing operation. For any operation  $opt_i$ , its set of error recovery operations  $\mathcal{R}_i$  can be derived by the procedure presented in Figure 2.7. According to above discussion, we can derive the set of recovery operations  $\mathcal{R}_i$  for any operation  $opt_i$ .

Based on the relationship between operations in the initial sequencing graph, we can further add edges between operations in the set  $\mathcal{R}_i$ , and thus derive the error recovery graph  $G_{Re_i}$  for  $opt_i$ . If an error occurs in  $opt_i$ , we will re-execute operations in  $G_{Re_i}$  for error recovery.

FIGURE 2.7: Pseudocode for determining the recovery operation for  $opt_i$ .

It is important to note that some electrodes on the biochip are intentionally left unused and reserved for storage of backup droplets. An example is shown in Figure 2.6(b); all electrodes on the boundary of the chip are used as storage cells. Thus backup droplets can be easily transported on the biochip.

### 2.3.2 Reliability consideration in error recovery

When an error is detected during the execution of a bioassay, simply re-executing the operation for which an error occurred is not efficient to ensure reliable operation. This is because the errors that occur during the execution of a bioassay usually are caused by defects involving electrodes; thus, multiple errors may occur in the same region of the biochip at different times. Two examples are provided below to illustrate the errors caused by the charge-trapping phenomenon and DNA fouling.

When the electrodes of a digital microfluidic biochip are actuated excessively, physically-trapped charge and residual charge may lead to reliability problems [46][45]. Charge trapping is a phenomenon in which charge is trapped and concentrated in the dielectric insulator of the chip. It can lead to a reduction in the electrowetting force and malfunctions in the execution of the bioassay. An example is shown in Figure 2.8(a).

Suppose Electrode 1 has a trapped charge in its dielectric insulator layer, while Electrode 2 and 3 do not suffer from charge sharing. In order to implement a splitting operation, high voltages are applied on Electrode 1 and Electrode 3. However, the charge trapped on Electrode 1 will reduce the electrowetting force. The droplet

FIGURE 2.8: (a) An error caused by the phenomenon of charge trapping; (b) splitting operation with droplets with unbalanced volumes; (c) an error caused by DNA fouling on the surface of a biochip.

will be split by unequal forces, and the two resulting droplets may have unequal volumes; see Figure 2.8(b). If we simply re-execute the splitting operation and continue to use Electrode 1, additional errors may result. Even worse, the charge-trapping phenomenon eventually may cause permanent dielectric degradation of the electrode [46][45]. Thus, once an error is detected, the electrode at which the error occurred must no longer be used to implement fluid-handling operations in order to ensure the reliability of the biochip.

When droplets contain macromolecules, such as DNA, they may foul the surface of the electrodes [55]. As a result, droplet concentration can change in undesirable ways. If we continue to use these contaminated electrodes, other droplets may also be contaminated. An example of this is shown in Figure 2.8(c). The region where DNA fouling occurred is used as part of a mixer, and the concentrations of the output droplets of the mixing operation may be abnormal.

We use a simple strategy to ensure a reliability-driven error recovery. When an error is detected, we update the execution of the bioassay as follows:

- The operation with error is re-executed.

- The electrodes that may lead to errors will not be used in other operations. Note that for each operation, the on-chip resources occupied by it are all recorded by the control software. Thus depending on the error droplet, it is easy to backtrace to the region where error occurs. We consider all electrodes in this region as the possible locations for defects. These electrodes will therefore be discarded.

## 2.4 Error recovery and dynamic re-synthesis

With the availability of hardware that can send feedback to the control software, it is now necessary to design physical-aware software that can analyze sensor data and dynamically adapt to it. Adaptations include updates for the schedule of fluid-handling operations, resource binding, module placement, and droplet routing pathways.

The task of the control software includes two phases: the first phase is off-line data preparation before the execution of bioassay and the second phase is on-line monitoring for the fluid-handling operations as well as dynamic re-synthesis of the bioassay. Details are presented below.

### *2.4.1 Off-line data preparation before bioassay execution*

The first step in data preparation is to convert the sequencing graph of the bioassay to a directed acyclic graph (DAG) and store it in memory for use by the control software. In this DAG, the vertices represent microfluidic handling operations and the edges represent precedence relations between operations. The predecessors and successors of any operation can be determined by performing depth-first search on the graph [56].

The second step in data preparation is to assign error thresholds for each operation. These thresholds are determined by the requirement of precision for the bioassay and they are stored as a table in memory for use by the control software. During bioassay execution, if a detection result is outside the range of pre-assigned threshold values, we conclude that an error has occurred at the corresponding operation.

Table 2.1: Synthesis results for the bioassay shown in Figure 2.1(a).

Operation	Start time	Stop time	Resource	Location
Mix 1	6	12	3×2 mixer	(2, 6)
Mix 2	0	6	2×3 mixer	(2, 5)
Mix 3	0	10	2×2 mixer	(6, 2)
Mix 4	12	15	4×4 mixer	(4, 6)
Mix 5	15	18	4×2 mixer	(4, 6)

The last step in data preparation is the initial synthesis step for the bioassay. In this procedure, we map the sequencing graph of the bioassay and on-chip resources to the scheduling, resource binding, module placement, and droplet routing results for each operation.

For a sequencing graph consisting of  $n$  operations, the synthesis result can be written as the following set:

$$\mathcal{S} = \{M_{opt_1}^*, M_{opt_2}^*, \dots, M_{opt_n}^*\}$$

where  $M_{opt_i}^*$ ,  $1 \leq i \leq n$ , is the synthesis output for the  $i$ th operation  $opt_i$ . The element  $M_{opt_i}^*$  can be viewed as an ordered 6-tuple:

$$M_{opt_i}^* = \langle ts(opt_i), te(opt_i), x(opt_i), y(opt_i), col(opt_i), row(opt_i) \rangle$$

where  $ts$  and  $te$  are the start time and end time of the operation, respectively;  $x$  and  $y$  are the x-coordinate and y-coordinate for the module that implements the operation;  $col$  and  $row$  are the number of columns and rows occupied by the operation in the array.

For an arbitrary operation  $opt_i$ , the order of elements in the tuple  $M_{opt_i}^*$  is defined. Thus we can use  $M_{opt_i}^*(\tilde{j})$  to represent the  $\tilde{j}$ th element in the tuple  $M_{opt_i}^*$ . For example, the start time of  $i$ th operation can be written as  $M_{opt_i}^*(1)$ , the x-coordinate of  $i$ th operation can be written as  $M_{opt_i}^*(3)$ , and the number of columns occupied by  $opt_i$  can be written as  $M_{opt_i}^*(5)$ .

For simplicity, we write the set of all operations in the bioassay as  $\mathcal{P}$ ; and we use  $\mathcal{C}$  to refer to the set of constraints that  $\mathcal{S}$  must satisfy, which include:

1. For any pair of operations  $opt_w$  and  $opt_v$ , if the two open intervals  $(M_{opt_w}^*(1), M_{opt_w}^*(2))$  and  $(M_{opt_v}^*(1), M_{opt_v}^*(2))$  overlap, i.e.,

$$(M_{opt_w}^*(1), M_{opt_w}^*(2)) \cap (M_{opt_v}^*(1), M_{opt_v}^*(2)) \neq \emptyset,$$

which implies that operations  $opt_w$  and  $opt_v$  are implemented concurrently. It is important to note that multiple operations cannot share on-chip resources (including electrodes and dispensing ports) at the same time. Thus  $opt_w$  and  $opt_v$  must satisfy following constraint:

$$(M_{opt_w}^*(3), M_{opt_w}^*(3) + M_{opt_w}^*(5)) \cap (M_{opt_v}^*(3), M_{opt_v}^*(3) + M_{opt_v}^*(5)) = \emptyset,$$

$$\cup$$

$$(M_{opt_w}^*(4), M_{opt_w}^*(4) + M_{opt_w}^*(6)) \cap (M_{opt_v}^*(4), M_{opt_v}^*(4) + M_{opt_v}^*(6)) = \emptyset,$$

i.e., their corresponding modules cannot overlap with each other.

2. For any pair of operations  $opt_w$  and  $opt_v$ , if  $opt_w$  is the predecessor of  $opt_v$ , then  $opt_w$  must be completed earlier than the start time of  $opt_v$ , i.e.  $M_{opt_v}^*(1) \geq M_{opt_w}^*(2)$ .

The completion time of the bioassay can be written as:

$$C_p = \max_{opt_i \in \mathcal{P}} \{M_{opt_i}^*(2)\}$$

Thus the synthesis of the biochip can be viewed as an optimization problem. The inputs are the set of operations  $\mathcal{P}$  and the set of constraints  $\mathcal{C}$ . The target is:

$$\text{minimize: } \max_{opt_i \in \mathcal{P}} \{M_{opt_i}^*(2)\}$$

Previously published CAD methods for digital microfluidic biochip have proposed several algorithms to solve this optimization problem. For example, the PRSA-based synthesis algorithms can be used to quickly derive optimized synthesis results [57].

After the optimized synthesis results are derived, the off-line data preparation step is completed. The bioassay is next executed according to the initial synthesis result, and the next step is the on-line monitoring of droplets.

- 
- 1: Derive the graph  $G_{original}$  by deleting edges between the erroneous operation and its immediate predecessors in original sequencing graph;
  - 2: Derive the error recovery graph  $G_{Re_i}$  for  $opt_i$ ;
  - 3: Copy  $G_{Re_i}$  and label the nodes with different names;
  - 4: Derive the union graph for  $G_{Re_i}$  and  $G_{original}$ ;
- 

FIGURE 2.9: Pseudocode for adjustment of the sequencing graph.

#### 2.4.2 On-line monitoring of droplets and re-synthesis of the bioassay

During the execution of the bioassay, the control software must implement the following steps.

##### **Step 1: Error Identification**

For the CCD camera-based sensing system, the software can carry out a real-time monitoring of all droplets on the biochip. The colors and diameters of the droplets are detected simultaneously by the CCD camera and evaluated for comparisons. Thus, error recovery is triggered as soon as an error occurs.

##### **Step 2: Update of Sequencing Graph**

When an error occurs, the control software determines the required recovery operations. According to the above discussion, if an error occurs during a reversible operation, the recovery process is simple. For non-reversible operations, the control software must search the preceding operations until it finds an operation that can provide backup droplets to feed the inputs of the recovery subroutine. As mentioned above, when an error occurs during the implementation of operations, the software will adjust the sequencing of the bioassay according to the category of operation. The pseudocode for the adjustment of the sequencing graph is shown in Figure 2.9. The definition of error recovery graph  $G_{Re_i}$  for operation  $opt_i$  can be found in Section 2.3.1. The update of the sequencing graph for errors that occur during the operations of Categories I, II, and III are shown in Figure 2.10. The categorization of operations can be found in Section 2.3.1.

It is important to note that, for some operations, the recovery subroutines may change depending on the error. For example, operation 7 in Figure 2.6(a) generates two droplets; one of them is used in the subsequent reaction and the other is stored on chip as the “backup droplet”. If a single error occurs at operation 14, the biochip will

FIGURE 2.10: Update of the sequencing graph corresponding to error operations of Categories (a) I; (b) II; and (c) III.

re-execute operations 8, 9, 10 and 12. However, if an error occurs at a predecessor of operation 14, the recovery subroutine for operation 14 will be different. For example, when an error occurs at operation 9, the backup droplet of operation 7 will be used as the input for error recovery. If another error occurs afterwards at operation 14, there is no more backup droplet available at the output of operation 7. Thus the recovery subroutine of operation 14 has to be expanded and it will now include operation 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, and 12. Therefore the recovery steps are completely different from the case when an error occurs at operation 14.

After the recovery subroutine of an operation is determined, the control software will update the sequencing graph and the corresponding DAG, and then the dynamic re-synthesis step will be implemented.

### Step 3: Dynamic Re-synthesis

In the cyberphysical system envisioned here, when an error is detected at a checkpoint, it will trigger the generation of a new mapping of the remaining steps (including proper handling of intermediate results) of the bioassay. This process is referred to here as *re-synthesis*, on the basis of the initial design obtained from the *a priori* synthesis step. The requirements for the process of re-synthesis are:

- The interruption of other operations should be avoided. Consider the following example. For the bioassay with synthesis results shown in Table 2.1, suppose an error recovery process is triggered by an error in operation Mix 3 at time instance 10. When the error recovery process is triggered, operation Mix 1 is

being implemented. In order to avoid the interruption of Mix 1, in the new synthesis results, the schedule and resource assignment results for Mix 1 should be the same as in the initial synthesis results.

- The electrodes at which an error has been deemed to have occurred should be bypassed in the new synthesis results.
- The completion time of the bioassay should be optimized.

To satisfy these requirements, we propose two re-synthesis strategies for dynamic re-synthesis. The first strategy is based on a local greedy algorithm, and the second is a PRSA-based, global optimization algorithm [32].

For the greedy algorithm, the first step is to determine all operations that must be adjusted in the re-synthesis result. These operations include the operations in the error recovery graph, the erroneous operation, and the set of subsequent operations that will be implemented on electrodes with defects in the initial synthesis result. Other operations will be executed based on the initial synthesis result.

Since the synthesis results for part of the operations are fixed, dynamic re-synthesis on the microfluidic array can be modeled as the *module placement with obstacles* problem. Here the operations that are implemented based on the initial synthesis result are fixed *a priori* as the “obstacles” while the other operations that are necessary for recovery are derived through re-synthesis and placed in the remaining available chip area in a greedy fashion. The detailed steps are described below.

First the control software places all operations that need to be re-scheduled in a priority queue based on topological sort. These operations include error recovery operations and all successors of the erroneous operation. Then the software assigns a priority for each operation in the queue. The “deepest” operation in the subroutine (i.e., the operation at the bottom of the list generated by topological sort) is assigned the lowest priority while the “shallowest” (at the top of the list produced by topological sort) operation is assigned the highest priority in the queue.

Next the control software needs to allocate on-chip resources to these operations.

Here our on-chip resource set  $R$  changes with time  $t$ . The control software will search for available resources at the current time for the operation with the highest priority. For example, if the operation with the highest priority is a mixing operation, then the system will search for an available  $m \times n$  cell array that is not occupied from current time  $t$  to  $t + \Delta t$ . Here  $\Delta t$  is the time needed for the operation in the  $m \times n$  cell array. If suitable idle resources are available, resource binding will be successful and the start time of the operation will be deemed to be the current time. Otherwise, the operation has to be delayed until there are available resources. If multiple resources are available at the same time, the control software will randomly choose one and bind it to the corresponding operation. After resource binding and start/stop time of the operation are determined, the operation will be removed from the priority queue.

Note that the above steps can also be used to generate re-synthesis results, when multiple errors are detected at the same time. In this situation, multiple recovery processes are triggered at the same time and the control software generates a priority queue for each recovery process. After these priority queues merged, the control software assigns a priority for each element based on topological sort. Finally, the control software determines new synthesis results for every operation in the merged priority queue.

For a microfluidic biochip with an  $M \times N$  electrode array and  $P$  dispensing ports, the computational complexity of searching for available resources (i.e. “the maximum empty rectangle”) in this re-synthesis algorithm is  $O(MN + P)$ . Since we can view the number of dispensing ports as being constant and we are interested in algorithm scalability for large arrays, the worst-case complexity is  $O(MN)$ . This is because the software will exhaustively search each electrode/dispensing port in the array and check whether it is available. The computational complexity for other parts of the algorithm are all  $O(1)$ . Hence the overall computational complexity of the re-synthesis algorithm is  $O(MN)$ . The pseudocode for the re-synthesis procedure is shown in Figure 2.11.

An example of re-synthesis is shown in Figure 2.12. Figure 2.12(a) shows the

schedule corresponding to the sequencing graphs in Figure 2.1(a). Figure 2.12(b) and Figure 2.12(c) both show the schedules corresponding to the sequencing graph in Figure 2.1(b). For the sake of clarity, we only show the schedule for mixing operations. Here Figure 2.12(b) is the schedule obtained using the error-recovery algorithm of From Figure 2.12(b), we can see that mixing operation Mix 1 is halted for 10 time slots when error recovery operations are executed. The completion time of the bioassay shown in Figure 2.12(a) is increased from 18 time slots to 28 time slots, which can be unacceptable for many applications. The dynamic scheduling result corresponding to Figure 2.1(b) is shown in Figure 2.12(c). When the error is detected at the output of Mix 3 at time 10, the Mix 3 at time 10, the ongoing operation Mix 1 is executed based on the initial synthesis result. We assume that the computing time to generate the new synthesis result is 1 time slot. In practice, computation time is at least an order of magnitude less than the fluidic operation time. Then at time 11, the control software will generate new synthesis result based on the updated Figure 2.1(b). As shown in Figure 2.12(c), Mix 1 is completed at time 12 without being interrupted and the experiment is finished at time 18. Thus the bioassay is executed “seamlessly” without any time penalty or interruption of other operations.

The re-synthesis problem can also be solved using the PRSA-based global optimization method from [32]. The inputs and constraints of the re-synthesis problem are different from the initial synthesis problem introduced in Section 2.3.1. Suppose the set of operation for the re-synthesis problem is  $\mathcal{P}'$  and the set of constraints is

(a)

(b)

(c)

FIGURE 2.12: (a) Scheduling result when no error occurs; (b) scheduling when an error occurs in Mix 3. Mix 1 is halted when error operations are executed; (c) scheduling when an error occurs in Mix 3. Here dynamic synthesis strategy is applied at time 10 and error recovery operations begin at time 11.

$\mathcal{C}'$ . We can derive  $\mathcal{P}'$  and  $\mathcal{C}'$  based on  $\mathcal{P}$  and  $\mathcal{C}$  introduced in Section 2.3.

We first define a operator  $\mathcal{T}$  on the set  $\mathcal{P}$ .  $\mathcal{T}$  is a mapping from the set of all operations to the set of operations that have already started at time instant  $t$ .

$$\mathcal{T}(t) : \mathcal{P} \rightarrow \mathcal{P}(t) = \{opt_i | M_{opt_i}^*(1) \leq t\}$$

When an error is detected at time instant  $t$  in operation  $opt_i$ , the set of operations that need to be re-synthesized can be written as  $\mathcal{P}' = \mathcal{P} \cup \mathcal{R}_i \cup \tilde{\mathcal{O}} - \mathcal{P}(t)$ . Here  $\mathcal{R}_i$  is the set of recovery operations corresponding to erroneous operation  $opt_i$ , and  $\tilde{\mathcal{O}}$  is the set of subsequently operations which will be implemented on electrodes with defect

in the initial synthesis result. The method for determining the operations in  $\mathcal{R}_i$  is introduced in Section 2.4.1. Then according to the module placement information included in initial synthesis result, and locations of electrodes with defects, operations in  $\tilde{\mathcal{O}}$  can be determined.

We write the new synthesis results for  $opt_i \in \mathcal{P}'$  as  $M'_{opt_i}$ . In addition to the set of constraints  $\mathcal{C}$ , the new synthesis must satisfy the constraint that the region where an error has been deemed to have occurred cannot be used any more.

The optimization problem for re-synthesis process can be written as:

$$\text{minimize: } \max_{opt_i \in \mathcal{P}'} \{M'_{opt_i}(2)\}$$

The above optimization problem can be solved by using the PRSA-based synthesis procedure introduced in [32]. Using this method, we can derive globally-optimized synthesis results with short assay completion time, but the CPU time is high of the order of 20 minute for a typical bioassay [40]. Thus, this method is not suitable for on-line computation of re-synthesis results.

## 2.5 Simulation results

In this section, we evaluate the re-synthesis approach for error recovery on representative bioassays that are especially prone to fluidic errors. We compare the completion time for the two sensing schemes; and the re-synthesis results derived by the greedy algorithm and the PRSA-based global optimization algorithm.

### 2.5.1 Preparation of plasmid DNA

First, we simulate the bioassay that is called “preparation of plasmid DNA by alkaline lysis with SDS-miniprep” [51][58]. During sample preparation, a mixture of three reagents is required. The three reagents are:

- $R_1$ : Alkaline lysis Solution I (50 mM Glucose, 25 mM Tris-HCl (pH 8.0), 10 mM EDTA (pH 8.0)).
- $R_2$ : Alkaline lysis Solution II (0.2 N NaOH, 1% SDS (w/v)).

FIGURE 2.13: Sequencing graph for sample preparation of plasmid DNA.

- $R_3$ : Alkaline lysis Solution III (5 M sodium acetate, glacial acetic acid).

The required concentration of the mixture is 0.22% of  $R_1$ , 0.44% of  $R_2$ , and 0.34% of  $R_3$ , which can be approximated to  $\frac{28}{128}$  of  $R_1$ ,  $\frac{56}{128}$  of  $R_2$ , and  $\frac{44}{128}$  of  $R_3$ . The sequencing graph to get the required concentration by mixing  $R_1$ ,  $R_2$ , and  $R_3$  is shown in Figure 2.13. This bioassay is mapped to a  $10 \times 10$  electrode array and all electrodes on the boundary of the array are used as storage cells.

The error-recovery capability of the cyberphysical microfluidic system can be evaluated on the basis of the bioassay completion time when errors are detected. We inject errors randomly into the chip during the execution of the bioassay and compare the completion time of the two sensing schemes. The results are shown in Figure 2.14. Here the completion time is derived from the greedy algorithm introduced in Section 2.4, and the results are the average of the values derived from repeating the experiments 10 times. For this case (no error recovery), if an error occurs during the bioassay, the final outcome of the entire experiment will be incorrect. As a result, the biochip has to be discarded, and the experiment must be repeated on a new biochip in order to correct the error. If we assume that re-execution of the experiment will be successful, the bioassay completion time will be twice as the completion time in the fault-free case. Based on these results, we note that error recovery can reduce the bioassay completion time, and the consumption of biochemical reagents/samples can be reduced.

In reliability-driven error recovery, the electrodes where an error is deemed oc-

FIGURE 2.14: Completion time for biochip with CCD camera-based sensing system, and the biochip without error recovery mechanism when errors are injected in the sample preparation of plasmid DNA.

FIGURE 2.15: Comparison for the completion time between reliability-driven and reliability-oblivious error recovery [51] when a  $1 \times 4$  subarray is defective in the sample preparation of plasmid DNA. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in simulation.

curred will not be used in other operations. On the contrary, for the reliability-oblivious error recovery process in [51], when an error occurs during execution, the region where error occurs will continue to be used in subsequent operations. As

FIGURE 2.16: Comparison between the completion time of reliability-driven and reliability-oblivious error recovery when a  $2 \times 4$  subarray is defective in the sample preparation of plasmid DNA. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in simulation.

discussed in Section 2.3.2, these electrodes with defects may further lead to more errors.

To compare between the completion time for reliability-oblivious and reliability-driven error recovery procedures, the following simulation was set up. In the reliability-oblivious error recovery, we randomly select one operation  $opt_{fe}$  as the first instance of error in the execution of bioassay. The electrodes that are used to implement  $opt_{fe}$  are referred to “electrodes with defects”. When another operation is implemented again on these electrodes with defects, we assume that there exists a probability  $P_{fail}$  that this operation will also fail. For a fixed value of  $P_{fail}$ , we simulate reliability-oblivious error recovery 15 times, and determine average completion time.

Figure 2.15 compares the completion time of reliability-driven error recovery and average completion time of reliability-oblivious error recovery for different values of  $P_{fail}$ . Here the randomly selected  $opt_{ef}$  is a mixing operation implemented on a

FIGURE 2.17: Completion time for biochips with CCD camera-based sensing systems and without error recovery mechanism when errors are injected in the sample preparation of interpolating mixing.

$1 \times 4$  electrode array. As expected, Figure 2.15 shows that the reliability-driven error recovery leads to shorter assay completion time in the presence of defects.

Next we randomly select another operation as  $opt_{fe}$  and run the simulation again. The electrodes that implement  $opt_{fe}$  now constitute of a  $2 \times 4$  electrode array. The simulation results are shown in Figure 2.16. We find that as expected, the average completion time for reliability-oblivious error recovery is higher when more electrodes are likely to be defective. On the other hand, the completion time of reliability-driven error recovery does not depend on the type of defect on the chip and keeps the minimum completion time.

### 2.5.2 Protein assays: interpolating mixing and exponential dilution

Next we evaluate re-synthesis and error recovery for two real-life protein assays. These assays lead to the dilution of a protein sample by using two methods, namely interpolating mixing and exponential dilution. The protocols and corresponding sequencing graphs for these two bioassays are described in [40].

FIGURE 2.18: Completion time for the bioassay of interpolating mixing (derived from two re-synthesis algorithms when multiple errors are injected).

When errors are injected in the sample preparation of interpolating mixing, the completion time of biochips with CCD camera-based sensing systems and without error recovery mechanism are shown in Figure 2.17. The bioassay is mapped to a  $10 \times 10$  electrode array.

Figure 2.18 reports the completion time when multiple errors are inserted during the interpolating mixing protocol. Note that the completion time defined here only includes time spent on fluid-handling operations, and excludes the CPU time spent on resynthesis. From Figure 2.18, we see that the completion time achieved by the PRSA-based algorithm and greedy algorithm are almost the same, but the CPU times for these two algorithms are different. The simulation was performed on a 2.6-GHz, Intel i5 processor with 6 GB of memory. Both re-synthesis algorithm are implemented on the basis of the same initial synthesis result. The CPU time needed was around 33 minutes for computing the re-synthesis results using PRSA, which was 10 times more than the bioassay completion time; while the CPU time was less than 5 seconds for the greedy algorithm, which was only 2.5% of the bioassay

completion time. The bioassay completion time derived by greedy algorithm is only slightly higher for the PRSA. Nevertheless, the greedy algorithm is more suitable for on-line re-synthesis because of low CPU time.

While the PRSA-based approach is less attractive for real-time decision making, it provides a useful calibration point for the greedy algorithm and shows that the latter’s effective for timely bioassay completion. Moreover, the PRSA-based method can serve as the basis for future error recovery methods based on precomputation and preloading of recovery schedules.

For the exponential dilution protocol introduced in [40], we evaluate the completion time for the reliability-driven and reliability-oblivious error recovery methods in Figure 2.19. First we randomly select one operation  $opt_{fe}$  as the first instance of error in the execution of bioassay, where  $opt_{fe}$  is a dilution operation implemented on a  $1 \times 4$  electrode subarray. Then for subsequent operations that are implemented on this electrode array with defects, we set  $P_{fail}$  as the probability that the operation will fail again. Then corresponding to each value of  $P_{fail}$ , we run the simulations 15 times, and derive the average completion time for reliability-oblivious error recovery. In contrast, the defective electrodes are bypassed in reliability-driven error recovery. Thus the completion time of reliability-driven error recovery is independent of  $P_{fail}$ . From the results shown in Figure 2.19, we find that reliability-driven error recovery reduces the bioassay completion time. At the same time, we avoid the problem that any given set of defective electrodes can lead to replicated errors, thus the number of errors in the bioassay is reduced. Hence less reagents/samples are consumed, leading to lower cost and higher reliability for the experiment.

## 2.6 Chapter summary and conclusions

In this chapter, we have shown how recent advances in the integration of a sensing system in a digital microfluidics biochip can be used to make biochips error-resilient. We have presented a cyberphysical approach for “physical-aware” system reconfiguration that uses sensor data at intermediate checkpoints to dynamically reconfigure the

FIGURE 2.19: Comparison between the completion time of reliability-driven and reliability-oblivious error recovery [51] when a  $1 \times 4$  defect array is injected in exponential dilution. The error bars show the maximum and minimum completion time for reliability-oblivious error recovery in the simulation.

biochip. Real-time experiment monitory techniques based CCD camera have been considered. Two different sensor-driven re-synthesis techniques have been developed to recompute electrode-actuation sequences, thereby deriving new schedules, module placements, and droplet routing pathways, with minimum impact on the time-to-response. These two methods have been compared in terms of bioassay completion time and CPU time needed for re-synthesis. The coordination between the physical-aware control software and the microfluidic biochip allows sensor data at intermediate checkpoints to be used as feedback to make decisions about completed operations, and dynamically reconfigure the biochip and optimize electrode actuation sequences for subsequent operations. The proposed approach has been evaluated through simulation and its effectiveness demonstrated for three representative protein bioassays.

## Real-Time Error Recovery Using a Compact Dictionary

In this chapter, we present a hardware-assisted error-recovery method that relies on an error dictionary for rapid error recovery. The error-recovery procedure and dynamic re-synthesis of a reaction, which is especially attractive for flash chemistry, can be implemented in real-time on a single-board microcontroller. In order to store the error dictionary in the limited memory available in the low-cost microcontroller, we describe two compaction techniques. We use three laboratorial protocols to demonstrate that, compared to software-based methods, the proposed dictionary-based error-recovery method has less impact on response time, and requires simple experimental setup, and only a small amount of memory.

This chapter is organized as follows. The research motivation for the hardware-assisted cyberphysical biochip is introduced in Section 3.1. The proposed algorithm for creation of the error dictionary is presented in Section 3.2. Section 3.3 introduces the generation of actuation matrices corresponding to synthesis solutions in the error dictionary. Section 3.4 describes the procedures for compaction of the error dictio-

nary. The implementation of dictionary-based error recovery on FPGA is introduced in Section 3.5. A fault simulation method with consideration of parameter variation in the fabrication process is discussed in Section 3.6. Simulation results are shown in Section 3.7, and conclusions are presented in Section 3.8.

### 3.1 Motivation and related prior work

Flash chemistry has emerged as a highlight of recent research in chemical synthesis, where reactions are rapidly carried out and carefully controlled in real-time to produce desired compounds with high selectivity [59]. It can be used as a powerful tool for drug discovery, clinical diagnosis, and novel material synthesis [59; 60; 61]. However, flash chemistry introduces the following challenges: (i) the underlying fast reactions (with time scales of less than a second) require highly precise time-control in each step of chemical synthesis, a requirement that is beyond the capability of today’s benchtop laboratory instruments; (ii) organic synthesis procedures require the precise manipulation of liquids in small volumes [59]. These challenges can be potentially tackled using miniaturized microfluidic biochips.

Digital (droplet-based) microfluidics is an emerging technology that enables the integration of fluid-handling operations and reaction-outcome detection on a biochip [23] and it is a potential candidate for the implementation of flash chemistry. Liquid droplets with picoliter volumes in a digital microfluidic biochip can be manipulated on an array of discrete unit cells [3]. Fluid-handling operations, such as dilution of samples and reagents [47], crystallization of protein molecules [62], and transportation of droplets, can be implemented on the biochip by applying appropriate voltages to the electrodes [18][23]. The sequence of actuation voltages is pre-determined (i.e., before the implementation of the fluid-handling operations), and they are stored in a microcontroller or in computer memory [63]. Under clock control, the microcontroller can transfer pre-loaded actuation data to the biochip, thereby making it

feasible for laboratory researchers to implement chemical experiments automatically on the biochip. Precise control of the reaction times of each step in the experiment also can be achieved [23]. Furthermore, operations implemented on the biochip can be reconfigured dynamically by reprogramming the actuation sequences [23]. The sequence of actuation voltages can be derived from bioassay protocols using synthesis methods [29; 34; 63; 64; 65].

To improve the quality of product droplets, a cyberphysical system implementation of a biochip was recently proposed in Chapter 2 [66]. Despite of its novelty and advantages, the error-recovery method proposed in [66] suffers from the following shortcomings:

1. It requires on-line re-synthesis, which involves software-based dynamic regeneration of electrode actuation sequences. Such a resynthesis step leads to increased bioassay response times when errors occur [66]. When on-line re-synthesis is carried out using software, all fluid-handling operations are interrupted. On the other hand, the reaction time for flash chemistry lies in the range of milliseconds to seconds. For example, in Swern-Moffatt-type oxidation, the reaction time is about 0.01 s at 20 °C [60]. For such organic synthesis, it is essential to precisely control reaction time; these reactions will fail due to the additional time introduced by re-synthesis [59][61]. Thus the cyberphysical system in [66] cannot be used for flash chemistry.
2. The error recovery approach in [66] must be implemented by the control software running on a computer, which increases the complexity of the cyberphysical system. The computer-in-loop is not always desirable, e.g., for field deployment and handheld devices.
3. The complex nature of the coupling between the biochip and the control software may introduce reliability problems. The communication between the

biochip and the software is implemented using three components connected in series: the peripheral circuit, the microcontroller, and the USB port of the computer. Each of these components can be a point-of-failure, resulting in reduced system reliability.

To overcome the above shortcomings, we propose a dictionary-based, hardware-assisted error-recovery method. The key idea in this method is to precompute and store recovery actuation sequences for all errors of interest that can occur during a bioassay. When an error is detected by on-chip sensors during the execution of a bioassay, the cyberphysical system can simply look up the recovery solution in the dictionary rather than performing on-line re-synthesis using an in-the-loop computer. This dictionary-based solution therefore reduces response time and enables flash chemistry.

The proposed dictionary-based error recovery approach can be implemented using the finite-state machine (FSM) shown in Figure 3.1. The control signals for the biochip is determined by the current state of the FSM; the state transition of the FSM is triggered by the analog feedback indicating that an error has occurred. The error dictionary plays the role of a precomputed database that links each possible state to the corresponding outputs. Entries in the dictionary record all possible errors and the re-synthesis results, which include the corresponding error recovery operations. When an error occurs, the cyberphysical system can utilize the dictionary and load the pre-computed synthesis results.

Since no software execution is needed for on-line error recovery, the need for a computer and the related interfaces can be eliminated. The dynamic adaptation of the synthesis results can be implemented by a program that executes on the single-board microcontroller or an FPGA, which integrates components such as the microprocessor, memory, programmable I/O interfaces, clock circuitry [67]. However,

FIGURE 3.1: The proposed finite-state machine control system implementation of the cyberphysical system. The FSM runs on the microcontroller or the FPGA, and its current state determines control signals applied on the biochip. A state transition of the FSM is triggered by the detection of error(s).

since the error dictionary needs to store re-synthesis solutions for errors of interest, the data volume can be high. Consider a typical protein dilution bioassay with 103 fluidic operations [68]. If we limit ourselves to errors involving at most two operations, the memory required for storage of the error dictionary without compaction can be as high as 28.75 MB. However, the memory on a low-cost FPGA is typically limited. For example, according to the datasheet of several widely-used FPGAs (which cost less than \$50), the capacities of their on-chip memories are less than 1 MB [69]. External memory devices can increase the size of total memory, however, their prices can be as high as the low-cost FPGAs [70]. According to the current market price list [70][71], the use of external memory devices may double the cost of the system. External memory devices will also increase the complexity of the board, and they require additional circuit-board wiring [72]. Therefore, the above solutions are not compatible with the goal of low-cost biochip platforms that can be used for field deployment and point-of-care clinical diagnostics.

In this chapter, we propose a compaction procedure for an error dictionary which includes re-synthesis solutions for all the possible error combinations in bioassay.

Then we compact sets of vectors (i.e., actuation matrices) stored in the dictionary in a lossless manner. After these two steps, the size of compacted dictionary in the above example can be reduced to only 0.96 MB.

### 3.2 Generation of the error dictionary

For any given set of errors that can occur in a bioassay, the error dictionary is generated using simulation before the execution of experiments. During simulation, erroneous fluidic operations are considered and the corresponding re-synthesis results are determined. These resynthesis solutions are stored as entries of the dictionary. The simulation and dictionary generation are both performed by a computer in the off-line data-preparation stage.

The error dictionary is stored in controller memory as a decision tree that records all possible consequences of errors, as shown in Figure 3.2. The dictionary has multiple levels and the entries at the  $k^{\text{th}}$  level correspond to all possible cases errors that can occur involving  $k$  operations. Suppose the total number of operations in the bioassay is  $N$  and no errors occur during error recovery. The number of entries in the  $k^{\text{th}}$  level of the dictionary can be as high as  $\binom{N}{k}$ . For large  $N$  and  $k$ , the size of the error dictionary and the CPU time spent on error-dictionary generation can both be prohibitively high. Therefore,  $k$  must be limited in practice. Here we consider up to two erroneous operations ( $k = 2$ ) in the bioassay. If more errors occur, the biochip must be discarded and the experiment repeated on a different biochip.

We next introduce the steps for generating the error dictionary level-by-level. First we carry out synthesis for the error-free case, which corresponds to Level 0 in Figure 3.2; next, based on the error-free solution, we insert errors in the simulation and derive entries in Level 1 and Level 2 of the dictionary.

FIGURE 3.2: Tree structure of the error dictionary. Entries at the  $k^{\text{th}}$  level of the dictionary correspond to all possible cases of errors that can occur involving  $k$  operations.

### 3.2.1 Dictionary entry for error-free case

The entry in Level 0 of the error dictionary corresponds to the solution obtained using high-level synthesis. In this process, the behavioral description of the desired bioassay protocol, which is modeled as a sequencing graph, is mapped to a design implementation in terms of a sequence of fluidic operations and the corresponding actuation sequences.

Published CAD methods for digital microfluidic biochips have proposed integer linear programming and heuristic algorithms to solve this optimization problem [68][29][57]. For example, the parallel recombinative simulated annealing (PRSA)-based synthesis algorithms can be used to derive optimized results [68].

Suppose all the droplets used in the bioassay of Figure 2.1(a) are stored on the biochip before the execution of the bioassay. The first entry in Table 3.1 shows the synthesis results derived by PRSA-based synthesis algorithms for all mixing operations of the bioassay shown in Figure 2.1(a) [68]. The start and end time

FIGURE 3.3: Module placement for the bioassay shown in Figure 2.1(a).

of operations are written as  $ts$  and  $te$ , respectively. Figure 3.3 shows the module placement corresponding to the synthesis of the error-free case in Table 3.1.

It is important to note that in Table 3.1, “resource” refers to the part of the electrode array occupied by the mixing operation. The location of a mixer is expressed in terms of the location of the electrode at the upper left corner of the mixer. For example, the upper left corner of the mixing module  $M_1$  is in the sixth row and second column; it includes an electrode array with two rows and three columns. Thus the mixer is described as a  $2 \times 3$  mixer at location  $(6, 2)$ .

In addition, most of the bioassay benchmarks in the literature require that all the input and output droplets for the mixing/dilution operations are droplets with unit volume [73][74], i.e., at the end of each mixing/dilution operation, the mixed droplet with twice the unit volume must be split into two unit droplets. During the synthesis procedure of bioassays, for each mixing/dilution module, a set of electrodes will be randomly selected as the “splitter” to split the mixed droplet. The splitter can be placed in an arbitrarily-chosen place inside the mixing/dilution module. Therefore, for two operations, even when their corresponding modules are overlapped with each other (e.g., operations Mix 4 and Mix 5 shown in Figure 3.3), their corresponding splitters may contain different sets of electrodes.

Table 3.1: Dictionary entries corresponding to single errors occurred during the execution of bioassay.

Errors	Synthesis result				
	Operation	$ts$ (s)	$te$ (s)	Resource	Location
State 0: Error-free case	Mix 1	6	12	2×3 Mixer	(6, 2)
	Mix 2	0	6	3×2 Mixer	(5, 2)
	Mix 3	0	10	2×2 Mixer	(2, 6)
	Mix 4	12	15	2×4 Mixer	(6, 4)
	Mix 5	15	18	2×4 Mixer	(6, 4)
State 1: Error in Mix 1	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Re-Mix 1	12	15	2×4 Mixer	(2, 2)
	Mix 4	15	18	2×4 Mixer	(2, 2)
	Mix 5	18	21	2×4 Mixer	(2, 2)
State 2: Error in Mix 2	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Mix 1	6	12	2×3 Mixer	(6, 2)
	Re-Mix 2	6	12	3×2 Mixer	(2, 2)
	Mix 3*	6	10	2×2 Mixer	(2, 6)
	Mix 4	12	15	2×4 Mixer	(6, 4)
State 3: Error in Mix 3	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Mix 1*	10	12	2×3 Mixer	(6, 2)
	Re-Mix 3	10	20	2×2 Mixer	(2, 2)
	Mix 4	12	15	2×4 Mixer	(6, 4)
	Mix 5	20	23	2×4 Mixer	(6, 4)
State 4: Error in Mix 4	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Re-Mix 4	15	18	2×4 Mixer	(2, 2)
	Mix 5	18	21	2×4 Mixer	(2, 2)
State 5: Error in Mix 5	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Re-Mix 5	18	21	2×4 Mixer	(2, 4)

\* These operations can be interrupted as part of error recovery.

### 3.2.2 Dictionary entries for single-operation errors

By inserting an error in the bioassay and recording the corresponding re-synthesis results, we can get the entries in Level 1 of the error dictionary. The re-synthesis problem can also be solved using the PRSA-based global-optimization method [68] while the CPU time is relatively long [66].

In [66], the algorithm for deriving new sequencing graph with error recovery

operations is proposed. Based on the synthesis result in the error free case, the newly added operations for error recovery can be “inserted” into the synthesis result of the error free case in a greedy fashion [66]. Therefore, the re-synthesis results for error recovery can be generated with short CPU time.

By explicitly analyzing all possible situations corresponding to all the potential single errors that can occur for a bioassay, we can derive the entries in Level 1 of the error dictionary. For example, the sequencing graph shown in Figure 2.1(a) has five mixing operations, and, if we only consider errors in mixing and assume that only one error occurs during the bioassay, there are five error candidates. We can derive the error-recovery results for all of the potential errors and store the results during the “off-line data preparation” stage, as shown in Table 3.1. Suppose Table 3.1 is loaded into the memory of the FPGA; it determines the state transition of the FSM running on the FPGA. At time  $t = 0$ , the FSM comes into State 0, i.e. it begins to execute the bioassay according to the initial synthesis result. At time  $t_s = 6$ , operation Mix 2 is completed, the sensing system checks the output of Mix 2. If an error is deemed to have occurred, the FSM transits to the corresponding state (State 2) and loads the re-synthesis result that is stored in the error dictionary (the third entry in Table 3.1). It is important to note that the synthesis results for all operations in the second entry start from time  $t = 6$ . Since Mix 3 is being implemented when an error occurs at Mix 2, it will continue to be implemented according to the initial synthesis result. All operations that may be interrupted by the transition for the state of the controller are marked by “\*” in Table 3.1. In this manner, the controller can dynamically adapt and do re-synthesis of the on-chip chemistry by looking up entries in the error dictionary; the computational complexity of on-line re-synthesis of the bioassay is reduced to  $O(1)$ .

Note that each entry in the dictionary contains only the re-synthesis result from the time that the error is detected to the end of the bioassay. For example, the dic-

tionary entry that corresponds to State 1 shown in Table 3.1 records the re-synthesis result from the 12<sup>th</sup> second (i.e., the moment in time that the error occurs in operation Mix 1 is detected) to the 21<sup>st</sup> second (i.e., the moment in time that the entire bioassay is completed). The time span of this dictionary entry is 9 seconds. Based on the above discussion, we note that there are various time spans for the entries in Level 1 of the dictionary.

### 3.2.3 Dictionary entries for multiple-operation errors

Based on the re-synthesis solutions corresponding to single-error cases, we can further explicitly consider all the cases with more than one errors and generate the re-synthesis resolutions. Consider the dictionary entries shown in Table 3.1. Suppose an error has already occurred at Mix 1 and the FSM running on the FPGA has entered State 1. For the re-synthesis solution in State 1, there are three operations Re-Mix 1, Mix 4 and Mix 5; here Re-Mix 1 is the recovery operation for Mix 1. Since we assume that no errors occur in error recovery operations, here only Mix 4 and Mix 5 are considered as candidates for the next error, and we need to generate recovery solutions for both of them. Finally we get re-synthesis solutions corresponding to pairs of errors {Mix 1, Mix 4} and {Mix 1, Mix 5}; see Table 3.2. These solutions are stored as two entries at the second level of the error dictionary. The “parent node” of these two entries is the entry that corresponds to the solution for the single error in Mix 1.

Note that each entry that corresponds to the occurrence of multiple errors contains only the re-synthesis result from the moment in time that the latest error is detected to the moment in time that the entire bioassay is finished. For example, the dictionary entry that corresponds to State (1, 4) shown in Table 3.2 contains two error operations, i.e., Mix 1 and Mix 4. According to the synthesis results shown in Table 3.1, the error that occurs in Mix 1 is detected earlier than the error that occurs

Table 3.2: Synthesis results corresponding to a pair of errors.

Errors	Synthesis result				
State (1, 4): Errors in {Mix 1, Mix 4}	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Re-Mix 4	15	18	2×4 Mixer	(2, 2)
	Mix 5	18	21	2×4 Mixer	(2, 2)
State (1, 5): Errors in {Mix 1, Mix 5}	Operation	$ts$ (s)	$te$ (s)	Resource	Location
	Re-Mix 5	21	24	2×4 Mixer	(6, 4)

in Mix 4. Therefore, the dictionary entry records the re-synthesis result from the 15<sup>th</sup> second (i.e., the time moment that the error occurs in operation Mix 4 is detected) to the 21<sup>st</sup> second (i.e., the time moment that the entire bioassay is completed). The time span of this dictionary entry is 6 seconds.

### 3.2.4 Consideration of error-recovery cost and reduction in the number of dictionary entries

For low-cost disposable biochips, the cost of samples and reagents used in the experiments can be higher than the cost of biochips. When an error occurs on the biochip, the additional number of droplets needed in error recovery needs to be calculated; then the decision needs to be made on whether to recover from the error and continue the experiment, or discard the biochip and run the bioassay on a new chip.

While generating entries for the error dictionary, an evaluation process can be performed for determining whether an error is “worth being recovered”. Thresholds for the number of droplets consumed can be set before generating the error dictionary. Consider the following example. Assume that when there is no error in the bioassay, the number of droplets consumed is  $N_f$ , and the maximum number of additional droplets needed for error recovery ( $N_{max}$ ) is set as  $15\% \cdot N_f$ . When we generate the dictionary entry for operation  $O_E$ , if the corresponding simulation result indicates that the number of additional droplets needed for error recovery is more than  $N_{max}$ , then the entry for recovering the error in  $O_E$  will not be added into the dictionary. Therefore, only cost-efficient entries are recorded by the dictionary. These dictionary entries are donated as “effective entries” of the error dictionary.

### 3.3 Actuation matrix

In order to execute the bioassay based on a synthesized chip, the information of droplet routes and the schedules of operations must be programmed into the FPGA [34]. The synthesis results of the bioassay are mapped to electrode actuation sequences, in which each element represents the status of the electrode at a specific time. For an  $M \times N$  array, we can number the electrodes on the array as  $E_1, E_2, \dots, E_{MN}$ . If the completion time of the synthesis result is  $T$  clock cycles, the actuation sequences for all electrodes can be written in the form of an  $(M \times N) \times T$  matrix, referred to as the *actuation matrix* and denoted by  $\mathcal{A}$ . The status of electrode  $E_i$  at time  $j$  is represented by the element in the  $i^{\text{th}}$  column and  $j^{\text{th}}$  row of  $\mathcal{A}$ .

For an arbitrarily chosen operation  $opt_{\tilde{i}}$ , suppose it is implemented on electrodes  $E_{e_1}, E_{e_2}, \dots, E_{e_k}$  at clock cycles  $T_{t_1}, T_{t_2}, \dots, T_{t_l}$ , respectively. If we write the set of the indices of these electrodes as  $I = \{e_1, e_2, \dots, e_k\}$  and the indices of clock cycles as  $J = \{t_1, t_2, \dots, t_l\}$ , then  $I$  is a subset of  $\{1, 2, \dots, MN\}$  and  $J$  is a subset of  $\{1, 2, \dots, T\}$ . Thus the actuation matrix for  $opt_{\tilde{i}}$ , (which is referred as  $M_{opt_{\tilde{i}}}$ ), can be written as  $\mathcal{A}_{I,J}$ . It is a  $k \times l$  sub-matrix of  $\mathcal{A}$  that corresponds to the rows with index in set  $I$  and the columns with index in set  $J$ . According to the constraints of biochemical synthesis, no two operations can occupy the same electrode at the same time, thus for operations  $opt_{\tilde{i}}$  and  $opt_{\tilde{k}}$ , their corresponding sub-matrices  $M_{opt_{\tilde{i}}}$  and  $M_{opt_{\tilde{k}}}$  do not overlap with each other.

Next, we show how to determine the values of elements in the actuation matrices. We also estimate the percentage of non-zero elements in an actuation matrix. During the implementation of fluid-handling operations, the status of the electrodes can be “activated”, “deactivated”, or “don’t-care”. A “don’t-care” status is assigned to an electrode when it is not required to be either active or inactive. It is important to note that for various operations, the typical control voltages for activation statuses are different. For example, in [18], the lowest voltage required to dispense a 300 pl droplet from a reservoir is 11.4 V, while the actuation voltage required to move a droplet is 7.2 V. Thus in the memory of the controller, these non-zero elements of

FIGURE 3.4: Movement of droplets for (a) mixing; (b) splitting; (c) dispensing [16]. Step A to Step D show the procedure of pulling a droplet from the reservoir.

actuation matrices are recorded as the value of the corresponding control voltages. In the following parts, we use “0” and “X” to represent deactivated and “don’t-care” status of electrodes, respectively. We also use “ $v_1$ ” and “ $v_2$ ” to represent the activated status in terms of different voltages for electrodes in mixing and splitting operations. As shown in Figure 3.4(a), operation Mix 1 is implemented on an electrode array with two rows and three columns; at the end of mixing, the product droplet will be split into two smaller droplets, as shown in Figure 3.4(b). During the mixing operation, suppose the droplet is moved counterclockwise along the loop consisting of six electrodes. At each clock cycle, the droplet will be moved from the current electrode to an adjacent electrode. Suppose that at time instant (clock cycle)  $t_0$ , the droplet rests on electrode  $E_1$ . The actuation sequence for each electrode is now calculated and listed in Table 3.3, and the last row in Table 3.3 corresponds to the split operation after the completion of mixing. From Table 3.3, we find that at each time instance during mixing, there is only one electrode in the mixer that must be activated. Voltages applied to other electrodes are either “0” or “X”, and all the “X” terms can be replaced by “0”.

Next we can write the actuation sequences of operation Mix 1 as an actuation matrix  $M_{Mix_1}$ . The  $i^{\text{th}}$ -row vector in  $M_{Mix_1}$  depicts the status of  $E_1$  to  $E_6$  at the  $i^{\text{th}}$  clock cycle of Mix 1. Suppose the completion time for operation Mix 1 is 5 clock cycles and at the 6<sup>th</sup> clock cycle the mixed droplet will be split. Then  $M_{Mix_1}$  has  $6 \times 6$  elements. It can be written as:

Table 3.3: Actuation sequences for electrodes in the mixer.

Electrodes	1	2	3	4	5	6
Actuation sequences (ordered in time)	$v_1$	0	X	X	X	0
	0	$v_1$	0	X	X	X
	X	0	$v_1$	0	X	X
	X	X	0	$v_1$	0	X
			...	...		
	X	X	X	$v_2$	0	$v_2$

$$M_{Mix_1} = \begin{bmatrix} v_1 & 0 & 0 & 0 & 0 & 0 \\ 0 & v_1 & 0 & 0 & 0 & 0 \\ 0 & 0 & v_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & v_1 & 0 & 0 \\ 0 & 0 & 0 & 0 & v_1 & 0 \\ 0 & 0 & 0 & v_2 & 0 & v_2 \end{bmatrix}.$$

We see that each row in  $M_{Mix_1}$  has one or two non-zero elements, which is a general case in fluid-handling operations.

Figure 3.4(c) shows the steps involved in dispensing a droplet from an on-chip reservoir. In order to pull a droplet out from the reservoir, the electrodes in the transportation path are activated in sequence, as shown from Step *A* to Step *D* in Figure 3.4(c) for a fabricated chip [16]. This procedure is completed in four clock cycles. The droplet is formed by activating the electrodes on the outlet of the dispensing port. In this process shown in Figure 3.4(c), the liquid drop in the reservoir is deformed under the electrical force.

Based on the steps shown in Figure 3.4(c), we derive corresponding actuation matrix  $M_{Dis}$  for a dispensing operation. The matrix  $M_{Dis}$  has four rows and it includes a total of five non-zero elements.

Since for any two operations  $opt_{\tilde{i}}$  and  $opt_{\tilde{k}}$ , the corresponding sub-matrices  $M_{opt_{\tilde{i}}}$  and  $M_{opt_{\tilde{k}}}$  are non-overlapping, we can estimate the number of non-zero elements in the actuation matrix  $\mathcal{A}$  on the basis of the sub-matrices corresponding to all the operations in the bioassay. Suppose the working frequency of the biochip is  $f$  Hz ( $f$  usually varies from 1 to 100 [21]). Thus an operation that is completed in  $N$  seconds includes  $N \cdot f$  clock cycles. For the synthesis result shown in the first

entry of Table 3.1, the number of non-zero elements corresponding to the sequence matrix of each operation can be calculated according based on their execution time. Apart from the mixing operations, there are six dispensing operations that are not shown in Table 3.1, and each of them corresponds to a sub-matrix with 4 non-zero elements. Thus the total number of non-zero elements in the actuation matrix for the entire bioassay can be estimated by adding the number of non-zero elements for each operation. The resulting number is  $24 + 28f$ . On the other hand, since the completion time of the bioassay is  $4 + 18f$  clock cycles, the size of  $\mathcal{A}$  is  $(8 \times 8) \times (4 + 18 \cdot f)$ . Thus the percentage of non-zero elements  $P_{nz}$  in matrix  $\mathcal{A}$  can be calculated as:

$$P_{nz} = \frac{24 + 28 \cdot f}{(8 \times 8) \times (4 + 18 \cdot f)} \times 100\%.$$

Since the frequency range is  $1 \leq f \leq 100$  [21], we conclude that  $2.45\% \leq P_{nz} \leq 3.69\%$ . This implies that  $\mathcal{A}$  is a sparse matrix. Therefore, we can apply data-compaction algorithms to the actuation matrices in an error dictionary to reduce the storage requirement. Two algorithms that can be applied to compact error dictionaries will be introduced in Section 3.4. In Section 3.7.1, we will take the specific example of exponential dilution of protein to highlight that actuation matrices are sparse.

### 3.4 Compaction of the error dictionary

In this section, we describe two algorithms to compact actuation matrices of synthesis results for bioassay. Corresponding algorithms for de-compaction of error dictionary also will be discussed.

#### 3.4.1 *Compaction of the actuation matrix*

Suppose the actuation matrix  $\mathcal{A}$  is an  $(M \times N)$ -by- $T$  sparse matrix with  $\mathcal{K}$  non-zero elements, where  $M$  and  $N$  refer to the array dimensions and  $T$  is the number of clock circles for the assay. We describe two algorithms for the compaction of

the actuation matrix, and we define the compaction ratio as the number of elements before compaction divided by the number of elements in the matrix after compaction.

**Method I:** COO (coordinate list) compaction [75].  $\mathcal{A}$  can be stored as  $\mathcal{N}$  three-tuples. Each tuple records the row indices, column indices and numerical values of a non-zero element in the matrix. Thus the number of elements in the actuation matrix is compacted from  $NMT$  to  $3\mathcal{K}$ , and its compaction ratio  $R_I$  can be written as  $NMT/3\mathcal{K}$ . For example, the matrix  $M_{Mix_1}$  in Section 3.3 has 36 elements, and 7 of them are non-zero elements. Thus it can be compacted to 7 three-tuples, which have 24 elements in total:  $(1, 1, v_1), (2, 2, v_1), \dots, (6, 4, v_2), (6, 6, v_2)$ .

**Method II:** run-length encoding [76]. We apply run-length encoding to the actuation matrices. The actuation matrix of each dictionary entry can be reformatted to a signal sequence. The actuation sequence in which the same status value occurs in consecutive clock cycles can be compacted according to the single status value and the corresponding count number. For the actuation sequences for mixing and dispensing operations, we observe that “0” often occurs consecutively. Thus run-length encoding is applied to the “all-zero segments”, i.e., runs of 0s in the actuation matrix. In the compaction result, non-zero elements are represented by their values, and runs of 0s are represented by the corresponding count number. For example, the compacted vector “ $X_v a Y_v b$ ” stands for the following sequence:

$$X_v \underbrace{0\dots 00}_a Y_v \underbrace{0\dots 00}_b.$$

The  $\mathcal{K}$  non-zero elements will “divide” the  $MN$  column vectors in  $\mathcal{A}$  into at most  $MN + \mathcal{K}$  all-zero segments, and each of these segments is represented by its number of zeros. Thus the actuation matrix can be compacted to a vector with  $MN + 2\mathcal{K}$  elements, and its compaction ratio can be written as  $MNT/(MN + 2\mathcal{K})$ . For the matrix  $M_{Mix_1}$  shown in Section III, its first column is divided into two segments, where the first segment is the single non-zero element “ $v_1$ ” and the second segment is 5 consecutive “0”, so the first column can be compacted to “ $(v_1)(5)$ ”. Similarly, the second column is divided into three segments, and it is compacted to “ $(1)(v_1)(4)$ ”.

Based on the above discussion, the relative performance of Method I and Method

II depends on the relationship between  $MN$  and  $\mathcal{K}$ . When  $\mathcal{K} > MN$ , Method II offer higher compaction than Method I; otherwise, Method I is more efficient. Both compaction algorithms can be implemented when generating the error dictionary.

### 3.4.2 De-compaction of the error dictionary

Before the execution of the bioassay, the error dictionary must be compacted and stored in the memory of the FPGA. All compaction procedures described above are lossless and reversible. When an error occurs on the biochip is reported by the on-chip sensors, the controller accesses corresponding compacted re-synthesis outcome and restores it to the complete actuation matrix with the appropriate electrode actuation vectors.

The de-compaction procedure can be performed by de-compaction modules implemented on an FPGA. As explained above, by applying compaction Method I, the  $(M \times N)$ -by- $T$  actuation matrix is compacted to a  $1 \times \mathcal{K}$  vector. Each element in the vector represents a non-zero element in the original uncompact matrix, denoted by  $(i, j, v_{ij})$ , where  $v_{ij}$  is the non-zero value;  $i$  and  $j$  are the row and column indices of the non-zero element.

Since at each time moment, we only need to apply actuation signals on  $M \times N$  electrodes, the actuation matrix is de-compacted “segment by segment” during the de-compaction procedure. Here we assume that the memory space required for each element in the original actuation matrix is  $n_b$  bits. In the de-compaction module, an  $(M \times N \times n_b)$ -bit register is used to store the de-compacted  $M \times N$  actuation sub-matrix. Before applying the actuation matrix on the electrodes of the biochip, the data stored in the  $(M \times N \times n_b)$ -bit register is reset to zero. Next the de-compaction module “fills” non-zero elements into the  $(M \times N \times n_b)$ -bit register, i.e., the module assigns the elements in the  $1 \times \mathcal{K}$  vector to the  $(M \times N \times n_b)$ -bit register. When the de-compaction procedure of one  $M \times N$  actuation sub-matrix is finished, the corresponding actuation signals are applied to electrodes on the biochip. The data stored in the  $(M \times N \times n_b)$ -bit register will be reset to zero again, and the next segment in the compacted actuation matrix will be de-compacted.

The compaction results derived from Method II can be restored to the original actuation matrix in a similar way.

The clock for de-compaction and for writing data into the  $(M \times N \times n_b)$ -bit register can be as high as 16 MHz [69], while the clock frequency of the biochip is usually between 1 Hz and 100 Hz [21]. The frequency of the FPGA is several orders of magnitudes higher than the frequency of fluid-handling operations, hence the total time needed for accessing the dictionary, de-compaction, and transfer of data from the FPGA to buffers in the peripheral circuit is negligible compared to the clock cycle of the biochip.

### 3.5 Implementation of dictionary-based error recovery on FPGA

The circuitry for error recovery on a cyberphysical microfluidic biochip consists of four main modules, i.e., 1) the sensing module for the detection of errors, 2) the memory module for the storage of the error dictionary, 3) the FSM module for the dynamic adjustment of actuation sequences when errors occur, and 4) the de-compaction module for decoding the actuation matrices. All four modules can be implemented on an FPGA.

The modules are described using Verilog, and synthesized using Quartus II [77]. All functional and timing simulations for the modules are performed using ModelSim-Altera [78]. The FPGA used in the simulation belongs to the family of Cyclone IV [79], which includes a series of devices. The maximum numbers of I/O ports and logic elements provided by these devices are different [79]. While synthesizing the modules, Quartus II selects the suitable devices based on the required number of I/O ports and logic elements. The maximum on-chip memory that the family of Cyclone IV can provide is 0.83 MB.

The interconnection of the modules is presented in Figure 3.5, and the detailed implementation of these modules in an FPGA is discussed below.

FIGURE 3.5: Modules and their interconnections for the dictionary-based error recovery system.

### 3.5.1 Sensing module

The sensing module can be designed on a biochip based on different sensing techniques. Here, we use the imaging-based droplet detection method as the example to illustrate the implementation of sensing modules in FPGA. Note that the error-recovery algorithm approach proposed in this work is general and it can be applied to cyberphysical biochips with various sensing systems.

In Chapter 2, an imaging-based droplet-tracking algorithm is discussed. During the execution of the bioassay, an image sensor is used to monitor the entire biochip. Based on the images captured by the image sensor, the control software can search for droplets automatically by “template matching” (Section 2.2.1). The acquired images are first converted to 2-dimensional matrices. For example, an image with  $M_w \times N_w$  pixels will be converted to an  $M_w \times N_w$  matrix, in which each element represents one pixel of the image.

An image of a typical droplet on the biochip is selected as the “template” (which is written as  $T$ ). Each time, the software crops a sub-image ( $T_s$ ) from the image of the entire biochip. The template image and the cropped sub-image are considered as two vectors, and the correlation index of these two vectors can be used to represent the similarity between the template and the cropped sub-image. In order to locate the positions of droplets on the biochip precisely, the correlation index is calculated on a pixel-by-pixel basis [66]. Therefore, if the image for the entire biochip has  $M_w \times N_w$

pixels and the template image has  $M_s \times N_s$  pixels, the calculation of the correlation factor between the template image and the cropped sub-image must be implemented  $(M_w - M_s) \times (N_w - N_s)$  times. The computational complexity of droplet tracking is significant when there is a large number of pixels in the image of the entire biochip, and the image-based droplet-tracking method must be performed by the software on a computer [66].

Based on the characteristics of the digital microfluidic biochip, the image-based droplet-tracking procedure can be simplified and accelerated, and all of the calculations can be performed on the FPGA. The movements of droplets on the biochip are synchronized under clock control. At the beginning of each clock cycle, all the droplets are expected to stay at the center of their corresponding electrodes. Then, actuation signals are applied to all electrodes at the same time, and the droplets are moved towards their destination electrodes concurrently. At the end of the clock cycle, all the droplets are expected to stay at the center of their destination electrodes. Therefore, in order to monitor the movement of droplets, we only need to check the position of each droplet once at the beginning of each clock cycle.

Since the biochip consists of a discrete electrode array, the image of the entire biochip can be partitioned into sub-images, and each sub-image shows the status of one electrode. The template  $T$  is selected as the image of an electrode on which there is a typical droplet. Assuming that there are  $K$  electrodes on the biochip, the sub-images derived can be written as  $I_1, I_2, \dots, I_K$ . By comparing  $T$  with these  $K$  sub-images, the positions of the droplets can be determined. Therefore, at each clock cycle, the calculation for the correlation index between the template and the sub-image will be implemented only  $K$  times.

The calculation of the correlation index between two vectors can be implemented easily by the image-based droplet-tracking module. In our simulation, we use the picture of a biochip with 15 electrodes to test the functionality of the module, and each sub-image contains  $27 \times 21$  pixels. When the working frequency of the FPGA is 20 MHz, the time spent on checking all 15 sub-images is  $4.5 \times 10^{-4}$  second, while the time to move a droplet from one electrode to another adjacent electrode is usually

between  $10^{-2}$  second and 1 second [21]. The time spent on checking the droplet is negligible when compared with the clock period of the biochip. Hence, the imaging-based droplet-tracking module implemented on FPGA can be used as a real-time sensor for the biochip.

### *3.5.2 Memory for storage of the error dictionary*

The error dictionary of the bioassay is stored in the read-only memory (ROM) of the FPGA. During the fault simulation of the bioassay, entries of the error dictionary are generated, compacted, and then written into a “memory initialization file” (MIF). The MIF specifies the content for each memory cell in ROM. At the same time, a table that records the starting and ending addresses of each dictionary entry is generated and loaded into the module of the FSM (Figure 3.5).

After the compilation of the FPGA project, the contents of the ROM are initialized by the MIF, and they can no longer be changed. When the FSM sends the addresses of the memory cells to the ROM, the data stored in corresponding cells are sent as the output of the ROM.

### *3.5.3 FSM module*

As introduced in Section 3.1, automatic error recovery can be implemented by an FSM. The input of the FSM is the detection results from sensing module. The outputs of the FSM are the starting and ending storage addresses of the dictionary entry that must be applied to the biochip. When the detection module sends a signal indicating that an error has occurred, the FSM transits from one state to another state for error recovery. The starting and ending storage addresses of the dictionary entry that must be applied to the biochip are changed accordingly.

The output of the FSM is connected to the inputs of the ROM. When the FSM sends the addresses of the dictionary entry, the data that are stored in the corresponding memory cells are sent to the output of the ROM. Since the data stored in the ROM are the compacted dictionary entries, these data must be de-compacted before that can be applied to the electrodes on the biochip. Therefore, the output

Table 3.4: Resource report for synthesized modules.

	# Logic elements	# Combinational functions	# Logic registers	# Total registers	# Total pins
Image-based droplet tracking	4631	4627	230	230	22
De-compaction (Method I)	249	249	144	14	42
De-compaction (Method II)	42	42	31	31	42

of the ROM is connected to the input of the de-compaction module, as shown in Figure 3.5.

#### 3.5.4 De-compaction module

The working principle of the de-compaction module is introduced in Section 3.4.2. The input of the de-compaction module is the compacted actuation sequence, and the output is the de-compacted actuation signal sequence that can be directly applied on the biochip.

The de-compaction modules that correspond to both compaction Method I and Method II are both implemented by the FPGA. When the working frequency of the FPGA is set as 20 MHz, one dictionary entry with 930 elements, where each element is an 8-bit binary number, can be decoded in less than 50  $\mu s$ . Therefore, the time spent on dictionary de-compaction is negligible when compared with the time required to move a droplet from one electrode to an adjacent electrode.

#### 3.5.5 Resource report for synthesized modules

The modules are synthesized by Quartus II. The resource reports for the synthesized droplet-tracking module and the de-compaction module are listed in Table 3.4. The FPGA resource occupied by the synthesized controller module depends on the total number of states in the FSM. The relationship between the number of states and the number of logic elements is shown in Table 3.5. The actual FPGA used in the simulation is EP4CGX15BF14C6.

FIGURE 3.6: Splitting of a droplet: Both Electrode 1 and Electrode 3 are actuated, and electrowetting forces are generated on the surfaces of these two electrodes.

### 3.6 Fault simulation in the presence of chip-parameter variations

In this section, we examine the nature of the errors that occur in splitting operations and present a parameter variation-aware fault simulation algorithm. By considering the variations in the parameters of the biochip electrodes, the simulator can mimic erroneous behavior during the execution of bioassay.

As introduced in Section 3.1, error occurrence in the biochip is defined as the occurrences of droplets with abnormal volumes or concentrations. Experimental results with fabricated biochips show that the generation of abnormal droplets in asymmetric splitting operations is the primary cause of errors that occur in biochips [16]. Furthermore, as introduced in Section 3.2.1, splitting operations are frequently implemented in bioassays. Most of the errors that occur during the execution of the bioassay are caused by the asymmetric splitting operations [80]. As shown in Figure 3.6, to split the droplet on Electrode 2, Electrode 1 and Electrode 3 are

actuated at the same time. Two electrowetting forces, written as  $F_1$  and  $F_3$ , are generated on the surfaces of Electrode 1 and Electrode 3, respectively. The droplet on Electrode 2 will be split under  $F_1$  and  $F_3$ , which are applied in opposite directions.

The electrowetting force applied on a droplet can be written as [81]:

$$F = \left( \frac{\varepsilon_{rd}\varepsilon_{rh}}{t_h\varepsilon_{rd} + t_d\varepsilon_{rh}} \right) \frac{\varepsilon_0 V^2}{2} \frac{dA_p}{dx}, \quad (3.1)$$

where  $V$  is the voltage applied to the actuated electrode,  $x$  is the position of the droplet,  $t_d$  is the thickness of the insulator layer,  $t_h$  is the thickness of the hydrophobic layer,  $\varepsilon_{rd}$  is the dielectric constant of dielectric layer,  $\varepsilon_{rh}$  is the dielectric constant of the hydrophobic layer,  $\varepsilon_0$  is the permittivity of vacuum, and  $A_p$  is the area of the overlapping region between the droplet and the actuated electrode [81].

In an ideal situation, the droplet in Figure 3.6 stays at the center of Electrode 2 at the beginning of the splitting operation. The overlap region between the droplet and Electrode 1 ( $A_{p1}$ ) and the overlap region between the droplet and Electrode 3 ( $A_{p3}$ ) are the same, therefore we have:  $\frac{dA_{p1}}{dx} = \frac{dA_{p3}}{dx}$ . For Electrode 1 and Electrode 3, their parameters  $t_d$  and  $t_h$  are also the same. Thus the forces generated on the surfaces of Electrode 1 and Electrode 3 are symmetric, i.e.,  $\frac{\|F_1\|}{\|F_3\|} = 1$ . The droplet will be split over the two electrodes into droplets of equal size.

However, due to the randomness inherent in the fabrication process, the parameters  $t_h$  and  $t_d$  may vary from electrode to electrode, and the electrowetting forces generated on the surfaces of Electrode 1 and Electrode 3 may not be exactly the same. In this case, the droplet will be split under asymmetric forces.

When asymmetric forces are applied, the droplet on Electrode 2 may be split into two droplets that have unequal volumes [81]. For example, when we split a droplet whose volume is 2 units, if  $\frac{\|F_1\|}{\|F_3\|} = 1.10$ , the volumes of the droplets derived will be 1.13 units and 0.87 unit, respectively [81]. If the “standard” volume of a droplet is 1 unit, and the error limit for the volume of droplets is 10%, then both of these droplets will be abnormal. In this case, errors are generated on the biochip.

By considering the distributions of parameters  $t_d$  and  $t_h$  for the biochip, the simulator can mimic the behavior of splitting operations in the bioassay. For any electrode  $E_i$ , the thickness of the insulator layer is written as  $t_d(E_i)$ , the thickness of the hydrophobic layer is written as  $t_h(E_i)$ . For given distributions of parameters  $t_d$  and  $t_h$  for the biochip, and the given synthesis result of the bioassay, the simulator can calculate the ratio of the two electrowetting forces generated in each splitting operation.

We assume that the splitting operation  $O_S$  is performed by electrodes  $E_R$  and  $E_L$ . According to Equation (1), the ratio of the electrowetting forces generated on  $E_R$  and  $E_L$  (written as  $F_{E_R}$  and  $F_{E_L}$ ) can be expressed as:

$$\frac{\|F_{E_R}\|}{\|F_{E_L}\|} = \frac{(t_h(E_L)\varepsilon_{rd} + t_d(E_L)\varepsilon_{rh})}{(t_h(E_R)\varepsilon_{rd} + t_d(E_R)\varepsilon_{rh})}. \quad (3.2)$$

If the ratio of  $\|F_{E_R}\|$  to  $\|F_{E_L}\|$  is out of acceptable range, the splitting operation  $O_S$  will generate two droplets that have abnormal volumes. In this way, an error is generated during fault simulation. By running the fault simulation under parameter variations, we mimic the occurrences of errors during the execution of the bioassay.

### 3.7 Simulation results

In this section, we first present simulation results for three widely used laboratory protocols, namely exponential dilution of a protein sample, interpolation dilution of a protein sample, and mixing tree bioassay, respectively [68][74]. Then the simulation result of a new benchmark for a flash chemistry application is presented [82].

The error dictionaries for these four bioassays are generated, and the compaction algorithms for error dictionaries are applied. We also carry out fault simulation to mimic the occurrences of errors during bioassay execution.

#### 3.7.1 Exponential dilution of a protein sample

##### Generating error dictionaries

FIGURE 3.7: (a) The histogram for the number of extra droplets consumed in all possible situations of exponential dilution bioassay; (b) the histogram for the time spans of effective dictionary entries when  $N_{max} = 5$ .

The exponential dilution bioassay contains 103 operations. The sequencing graph and the detailed description of the bioassay can be found in [68] and it is the most complex benchmark that is available in the literature related to digital microfluidic biochips.

By applying the PRSA-based synthesis algorithm [68], the synthesis result for the bioassay can be derived. When running the bioassay on a  $10 \times 10$  electrode array and no erroneous operation occurs, the completion time is 208 seconds. Based on the synthesis result for the error-free case, the dynamic re-synthesis algorithm proposed in [51] is applied to generate the error dictionary.

When generating entries of the error dictionary, erroneous operations are inserted into the bioassay. By considering each operation as a possible erroneous operation, 103 dictionary entries with single errors that occurs in the bioassay are generated. If we set the upper limit for the number of erroneous operations to be two, the number of possible combinations of errors that must be considered is  $\binom{103}{2}$ , i.e.,  $(103 \times 102)/2$  (here we assume that errors will not occur in error recovery operations). Therefore, the total number of entries  $\mathcal{N}_e$  in the dictionary is given by:  $\mathcal{N}_e = 103 + (103 \times 102)/2 = 5356$ .

Table 3.6: Effective dictionary entries corresponding to different values of  $N_{max}$  in the exponential dilution bioassay.

$N_{max}$	No. effective entries	Coverage rate	Max. time span (s)	Min. time span (s)
2	4013	74.92%	222	5
3	4113	76.79%	230	5
5	4747	88.63%	237	5
8	5356	100.00%	237	5

The fault simulation is run on a 2.30 GHz Intel i3 dual-core processor with 8 GB of memory. The CPU time is 1925.7 seconds for generating the error dictionary. The histogram for the numbers of extra droplets consumed in these 5356 dictionary entries is shown in Figure 3.7(a). The maximum number of additional droplets consumed in the process of error recovery is 8.

When we consider the cost of error recovery, not all these 5356 dictionary entries will be selected as “effective entries” in the error dictionary. For some biochemistry experiments, the cost of precious samples and reagents can be greater than the cost of the biochips. If “too many” droplets are consumed in recovering from the error, running the bioassay on a new biochip may be more cost-effective. In this situation, the corresponding synthesis results will not be recorded in the error dictionary.

The parameter  $N_{max}$  denotes the maximum number of additional droplets that can be used in error recovery when we consider the cost of samples and reagents. When  $N_{max}$  is set as 2, 3, 5, and 8, the numbers of effective entries that are recorded in the dictionary are 4013, 4113, 4747, and 5356, respectively. The maximum and minimal time spans of these effective entries corresponding to different value of  $N_{max}$  can be found in Table 3.6. For example, when  $N_{max} = 5$ , the time spans of the 4747 effective dictionary entries vary from 5 seconds to 237 seconds. One of the dictionary entries with the shortest time span corresponds to the error that occurs at the 208<sup>th</sup> second; after recovering from the error, the entire bioassay is finished at the 213<sup>th</sup> second. Therefore, the time span of this dictionary entry is 5 seconds. One of the longest dictionary entries corresponds to two errors that occur at the 15<sup>th</sup> second and

22<sup>nd</sup> second, respectively; after recovering from these two errors, the entire bioassay finishes at the 259<sup>th</sup> second. Hence, the time span of this dictionary is 237 seconds. The histogram for the time spans of the 4747 effective dictionary entries is shown in Figure 3.7(b).

The “coverage rate” shown in Table 3.6 is defined as the ratio between the number of effective entries and the total number of entries in the error dictionary. Recovery for 74.92% of the errors that occur in a bioassay can be accomplished using no more than two extra droplets.

### **Estimation of the percentage of non-zero elements**

As discussed in Section 3.3 and Section 3.4, when the actuation matrices are sparse, we can apply compaction algorithms to reduce the size of the error dictionary. Here we estimate the percentage of non-zero elements in the error dictionary generated in Section 3.7.1.

According to the underlying physical principle of droplet operations, the number of actuated electrodes on the array can be estimated on the basis of the number of droplets that are currently being manipulated on the biochip. For example, if a droplet is scheduled to stay at its current position, the electrode under the droplet will be actuated to “anchor” the droplet while all other electrodes that are in contact with the droplet need to be deactivated. If a droplet is scheduled to be moved from one electrode to another electrode, the target electrode needs to be actuated while all the other electrodes that are in contact with the droplet need to be deactivated.

As the biochip contains a  $10 \times 10$  electrode array, at each time moment, the actuation signals applied on the electrode array can be represented by a  $10 \times 10$  actuation sub-matrix. Therefore, by calculating the maximum number of droplets that can be concurrently manipulated on the biochip at each time moment, an upper bound on the percentage of non-zero elements in an actuation sub-matrix can be derived. From the sequencing graph for the exponential dilution of a protein sample [68], we can find that the maximum degree of parallelism for fluid-handling opera-

Table 3.7: Compaction ratios of Method I and Method II corresponding to different values of  $N_{max}$  in exponential dilution bioassay.

$N_{max}$	$S_O$ (MB)	$\bar{R}_I$	$\sigma_I$	$S_I$ (MB)	$\bar{R}_{II}$	$\sigma_{II}$	$S_{II}$ (MB)
2	21.12	24.13	4.43	0.90	34.89	6.12	0.62
3	21.61	24.23	4.53	0.93	34.98	6.26	0.64
5	24.77	24.09	4.45	1.12	34.77	6.11	0.77
8	28.75	23.82	4.25	1.40	34.47	5.89	0.96

tions is as follows. We simultaneously implement eight mixing operations (and each mixing operation involves two droplets) and eight dispensing operations (and each mixing operation involves one droplet). Therefore, the maximum number of droplets can be concurrently manipulated on the biochip is calculated as  $2 \times 8 + 8 = 24$ . The maximum number of non-zero elements in each  $10 \times 10$  actuation sub-matrix is also 24, i.e., the maximum percentage of non-zero elements in the entire actuation matrix is 24%. It is important to note that this upper bound is independent of the number of errors occurred during the execution of bioassay. Therefore, we have shown that each actuation matrix generated in Section 3.7.1 is sparse.

### Compaction for error dictionaries

The error dictionary can be compacted by Method I and Method II proposed in Section 3.4. When we set the value of  $N_{max}$  as 2, 3, 5, and 8, the number of effective entries in the error dictionary are different. In Table 3.7, the original size of the “effective error dictionary” is written as  $S_O$ ; the mean values for the compaction ratios of all effective dictionary entries are written as  $\bar{R}_I$  (derived by Method I) and  $\bar{R}_{II}$  (derived by Method II), respectively; the standard deviations for the compaction ratio of all effective dictionary entries are written as  $\sigma_I$  (derived by Method I) and  $\sigma_{II}$  (derived by Method II), respectively. Finally, the sizes of the dictionary after compaction are written as  $S_I$  (derived by Method I) and  $S_{II}$  (derived by Method II), respectively.

From Table 3.7, we can find that the total memory required to store the original effective error dictionary is 21.12~28.75 MB, which is much larger than memory

FIGURE 3.8: (a) The histogram for the numbers of extra droplets consumed in the 233 runs in which 233 errors are generated; (b) the histogram for the time spans of entries in the 233 runs in which errors are generated.

available on an FPGA. After compaction, the final size of the compacted dictionary can be smaller than 1 MB.

### Fault simulation results

After the generation and compaction of the error dictionary, next we run fault simulation for the exponential dilution bioassay.

As discussed in Section 3.6, if the ratio of electrowetting forces are out of the acceptable range, abnormal droplets will be generated. It is important to note that, in the bioassay protocols, there is an underlying assumption that the splitting of a droplet is the last step of the mixing/dilution procedure, i.e., splitting operations are executed at the end of each mixing/dilution operation. If droplets with abnormal volumes are generated when splitting the droplet at the end of a dilution/mixing operation  $O_{M/D}$ , this situation is defined as “an error occurs in  $O_{M/D}$ ”.

In the fault simulation setup considered here, we set the distribution function of the Gaussian random variable  $R_c = (t_h \varepsilon_{rd} + t_d \varepsilon_{rh})$  as  $r_c \cdot N(1, 0.03^2)$ , where  $r_c$  is a nominal value, and  $N(1, 0.03^2)$  is the Gaussian distribution function with mean 1 and variance  $0.03^2$ .

Table 3.8: Comparison of response times and bioassay completion times.

Bioassay	Errors inserted	ONS [64]			Fast Online Synthesis [83]			Proposed method		
		Response time (s)	Execution time (s)	Total time (s)	Response time (s)	Execution time (s)	Total time (s)	Response time (s)	Execution time (s)	Total time (s)
Exponential dilution	Dlt <sub>26</sub>	0.21	222	222.21	0.22	240	240.22	~ 0	208	208
	Mix <sub>3</sub>	0.13	220	220.13	0.31	233	233.31	~ 0	213	213
	Dlt <sub>2</sub>	0.88	222	222.88	0.94	240	240.94	~ 0	216	216
	Dlt <sub>21</sub>	0.69	222	222.69	0.74	233	233.74	~ 0	208	208
	Dlt <sub>27</sub>	0.52	222	222.52	0.54	233	233.54	~ 0	208	208
Interpolation dilution bioassay	DsB <sub>2</sub> and Dlt <sub>18</sub>	0.48	203	203.48	0.43	237	237.43	~ 0	182	182
	Dlt <sub>18</sub> and Dlt <sub>19</sub>	0.46	196	196.46	0.45	230	230.45	~ 0	189	189
	Dlt <sub>2</sub> and Dlt <sub>29</sub>	0.27	196	196.27	0.30	230	230.30	~ 0	182	182
	Dlt <sub>8</sub> and DsB <sub>3</sub>	0.62	203	203.62	0.61	237	237.61	~ 0	182	182
	Dlt <sub>16</sub> and Dlt <sub>18</sub>	0.43	196	196.43	0.43	230	230.43	~ 0	187	187

For a typical biochip,  $t_d \varepsilon_{rh} \gg t_h \varepsilon_{rd}$  for  $R_c$  [18]; therefore, here the distribution function for  $R_c$  is estimated according to the process variance of  $t_d$ . For a typical biochip fabrication process, the average spread in  $t_d$  is 11 nm [84], while the value of  $t_d$  usually is 450 ~ 800 nm [18][84]. Therefore, using a normalized variance of 3% for  $R_d$  is justified.

When a droplet is split by electrowetting forces  $F_1$  and  $F_2$ , and  $\frac{\|F_1\|}{\|F_2\|} \geq 1.10$  (or  $\frac{\|F_2\|}{\|F_1\|} \geq 1.10$ ), we assume that an error occurs. We run the fault simulation procedure a total of 1000 times. Among the simulation results for the 1000 runs, one error occurs 233 times and none of these 1000 runs include more than one error.

For the 233 runs with errors, the histogram for the number of extra droplets consumed in error recovery and the total completion time of bioassay derived by the proposed error recovery method are shown in Figure 3.8 (a) and (b), respectively. As shown in Figure 3.8, for these 233 runs, the maximum number of droplets consumed in error recovery is 5; the maximum total completion time for the bioassay is 237 seconds.

Part of the simulation results for the 233 runs with errors can be found in Table 5.4. After the error is detected, the biochip can derive the re-synthesis results either by the Online Synthesis Strategy (ONS) [64], Fast Online Synthesis [83], or by looking up the prepared error dictionary. The response time in Table 5.4 is defined as the time spent in deriving re-synthesis solutions to recover the error. Here we assume that both ONS and Fast Online Synthesis are using the hardware setup presented in Figure 2.5, i.e., the biochip and the computer are connected via an FPGA/signle board controller. The response times of ONS and Fast Online Synthesis include the time spent on writing the new actuation matrices into the memory initialization files of the FPGA.

Note that during on-line re-synthesis, all fluid-handling operations for the bioassay are suspended. The execution time in Table 5.4 is calculated from the beginning to the end of the bioassay, without considering the CPU time spent in re-synthesis. Thus the total completion time for the bioassay is the sum of the response time and

the execution time.

From Table 5.4, we can find that the CPU time needed for performing on-line re-synthesis by both ONS and Fast Online Synthesis are longer than the proposed method. It is important to note that for the laboratorial experiments in biochemistry, the reaction time for each step in the chemical synthesis is often very short, and the intermediate products may degrade or decompose quickly [82][61]. Thus the increase in response time introduced by the on-line calculations required in [68][83] may have an adverse impact on reaction outcome [82][61]. Therefore, only the proposed dictionary-based method can recover from the error “seamlessly” and avoid the degeneration of intermediate products of the bioassay. It is important to note that, even though ONS and Fast Online Synthesis can achieve online re-synthesis, the calculation has to be performed on the computer. Therefore, they are not suitable for the low-cost cyberphysical system that has only a single board controller/FPGA.

### 3.7.2 Interpolation dilution of a protein sample

The interpolation-based dilution bioassay has 71 operations. When no error occurs, the execution time of the bioassay is 182 seconds, and 32 droplets are consumed in the bioassay. Assume that the number of errors occur in the bioassay is no more than 2, then the total number of cases need to be considered is  $\mathcal{N}_e = 71 + (71 \times 70)/2 = 2556$ . For these 2556 dictionary entries, the histogram for number of droplets consumed in error recovery is shown in Figure 3.9(a).

By setting different value for  $N_{max}$ , the number of effective entries in the dictionary will be different. For example, when  $N_{max}$  is set as 3, 5, and 8, the numbers of effective entries in the dictionary are 1727, 2156, and 2556, respectively. When  $N_{max} = 3$ , the histogram for the time span of effective dictionary entries is shown in Figure 3.9(b).

The error dictionary can be compacted by Method I and Method II proposed in Section 3.4. When setting the value of  $N_{max}$  as 3, 5, and 8, the corresponding simulation results are presented in Table 3.9. The parameters of Table 3.7 are defined in Section 3.7.1.

FIGURE 3.9: (a) The histogram for the numbers of extra droplets consumed in all possible situations of the interpolation-based dilution bioassay; (b) the histogram for the time spans of entries in the error dictionary for the interpolation-based dilution bioassay (when  $N_{max} = 3$ ).

Table 3.9: Compaction ratio of Method I and Method II corresponding to different values of  $N_{max}$  in interpolation-based dilution bioassay.

$N_{max}$	$S_O$ (MB)	$\bar{R}_I$	$\sigma_I$	$S_I$ (MB)	$\bar{R}_{II}$	$\sigma_{II}$	$S_{II}$ (MB)
3	14.29	20.51	0.97	0.84	29.83	1.53	0.58
5	17.51	20.74	1.05	0.94	30.19	1.67	0.64
8	21.72	20.77	1.03	1.02	30.27	1.64	0.70

In the realistic fault simulation setup considered here, we set the distribution function of  $R_c$  as  $r_c \cdot N(1, 0.035^2)$ . We run the parameter various-aware fault simulation for 1000 times. When a droplet is split by electrowetting forces  $F_1$  and  $F_2$ , and  $\frac{\|F_1\|}{\|F_2\|} \geq 1.10$  (or  $\frac{\|F_2\|}{\|F_1\|} \geq 1.10$ ), then we assume that an error occurs.

Among the simulation results of the 1000 runs, 426 runs have one error occur, 129 runs have two errors, and none of the runs lead to more than two errors. The simulation results corresponding to 5 runs can be found in Table 5.4. We can find that the response time as well as the total completion time of the bioassay are reduced using the proposed dictionary-based re-synthesis procedure.

### 3.7.3 *Mixing tree bioassay*

In this part, we present the simulation results for a biochemical benchmark designed in [74]. The sequencing graph of the bioassay can be found in [74], it represents a solution preparation procedure, which has seven different kinds of reagent. The final output is the droplet which has the mixing ratio of  $2 : 3 : 5 : 7 : 11 : 13 : 87$  [74]. The bioassay has 37 operations, and the number of droplets consumed is 10. When the bioassay runs on an  $8 \times 8$  array, the completion time of the bioassay is 60 seconds. For all the 740 dictionary entries, the numbers of droplets consumed in error recovery are no more than 4. This is because in the protocol of mixing tree bioassay, each mixing/dilution operation generates a redundant copy droplet. During error recovery, these redundant droplet can be utilized, and only a small number of extra droplets need to be dispensed.

For compaction Method I, the compaction ratios for the dictionary entries vary from 2.1 to 13.4, The average compaction ratio for these entries is 4.8 and the standard deviation is 3.2. For compaction Method II, the compaction ratios for the dictionary entries vary from 2.8 to 18.2, The average compaction ratio for these entries is 6.6 and the standard deviation is 4.4. The size of the complete error dictionary can be reduced from 6.15 MB to 1.18 MB (Method I) and 0.87 MB (Method II).

### 3.7.4 *Flash chemistry*

As introduced in [82], a microfluidic biochip is one of the promising hardware platforms for flash chemistry. In this subsection, the simulation results for two representative assays of flash chemistry are presented. The two assays are “synthesis of unsymmetrical diarylethenes” ( $\mathbb{S}_1$ ) and the “bromine-lithium exchange reaction of o-dibromobenzene” ( $\mathbb{S}_2$ ) [82]. The numbers of operations in  $\mathbb{S}_1$  and  $\mathbb{S}_2$  are 9 and 5, respectively. Here we assume that the two assays are concurrently executed on a  $10 \times 10$  electrode array.

As the reaction times in flash chemistry usually are very short, here we assume that the working frequency of the biochip is 100 Hz, and each mixing operation on

Table 3.10: Compaction ratios of actuation matrices of an assay in flash chemistry.

Errors inserted	Bioassay time (s)	No. elements in the dictionary entry	No. non-zero elements in the dictionary entry	$R_I$	$R_{II}$
$M_2$ in $\mathbb{S}_1$	0.32	3200	93	11.47	11.19
$M_4$ in $\mathbb{S}_1$	0.25	2500	86	9.69	9.19
$M_1$ in $\mathbb{S}_2$	0.19	1900	94	6.73	6.60
$M_2$ in $\mathbb{S}_2$	0.19	1900	87	7.28	6.93

a  $2 \times 4$  array takes 0.04 second [82]. Since dispensing each reagent/sample droplet takes 4 clock cycles [16], the completion time for each dispensing operation is set as 0.04 second. In the error-free case, the completion time of these three bioassay is 0.19 seconds.

As the total number of operations in the “combined bioassay” is 14, the number of dictionary entries we generated is  $\mathcal{N}_e = 14 + (14 \times 13)/2 = 105$ . The average response time for the proposed method is nearly zero. We have also derived the compaction ratios for all the dictionary entries, and part of the simulation results are shown in Table 3.10. We find that for this small assay, Method I is more effective than Method II.

### 3.8 Chapter summary and conclusions

In this chapter, we have described a dictionary-based hardware-assisted error recovery approach for flash chemistry based on digital microfluidic biochips. The proposed method minimizes the response time for error recovery, and provides precise control of on-chip experiments for chemical synthesis. The proposed error-recovery procedure and dynamic re-synthesis of a reaction can be implemented in real-time on an FPGA. In order to store the error dictionary in the limited memory available in the FPGA, we have presented two compaction techniques for reducing data volume. We have used four laboratorial protocols to show that, compared to software-based methods, the proposed dictionary-based error-recovery method has negligible impact on the time-to response. It also requires less complex experimental setup, and needs

only a small amount of memory on the FPGA board.

As part of future work, we will (i) explore applications of cyberphysical adaptation to microfluidics for cell sorting [85] and for chip cooling [86]; (ii) explore alternative methods (e.g., Huffman encoding [87]) for compacting the data in error dictionaries.

## Optimization of Polymerase Chain Reaction

### 4.1 Introduction

The amount of deoxyribonucleic acid (DNA) strands available in the biological sample is a major limitation for many genomic bioanalyses [88][89]. For example, in the study of gene dosage in tumor DNA by comparative genomic hybridization, the analysis procedure requires several hundred nanograms of DNA strands for fluorescent labeling [88]. It is impossible to obtain such a large amount of DNA strands directly from biological samples. To overcome this problem, the polymerase chain reaction (PCR) technique is used as the first step for these bioanalyses to amplify (replicate) the initial DNA strands [88][89][90]. Based on the categories of operations involved, the procedure of genomic analysis can be divided into two separate stages [91]. The first stage is the amplification of the target DNA strands; the second stage is the subsequent operations after DNA amplification, including mixing the droplet that contains DNA strands with other reagents, and detecting the concentration of intermediate product droplets.

Digital microfluidic biochips are used extensively for the quantitative analysis of

biomolecular interactions and they offer a viable platform for performing the two stages of the PCR procedure on the same chip layout [89]. Compared to conventional instruments and analyzers, the digital microfluidic biochip platform offers several advantages for implementing PCR. It can implement the complete PCR procedure seamlessly, and achieve short time-to-results, low reagent consumption, rapid heating/cooling rates, and integration of multiple processing modules [90][92]. The size and power consumption of the entire PCR system can also be reduced.

An example of a digital microfluidic biochip performing DNA amplification (i.e., the first stage of the PCR procedure) is shown in Figure 4.1 [89][93]. A “heated” region and a “cooled” region are created by thermal units (e.g., a heater). First, the droplets dispensed from the reservoir “PCR mix” are mixed with the biological sample that contains the target DNA strands. Next, the well-mixed droplet is allowed to pass through several alternating heating and cooling steps [89][93]. Each thermal cycle contains two steps, i.e., 1) heating the droplet, which separates the double-stranded DNA inside the droplet into two strands, called “DNA melting”; and 2) cooling the droplet, with each strand of the DNA working as a template for synthesizing new DNA strands, called “primer annealing”. In this way, the initial DNA strands can be amplified into millions of copies [89]. As the target DNA strands in the droplet are labeled with fluorophores, by measuring their intensity of the fluorescence with optical detectors integrated on the biochip, one can monitor the concentration of the DNA strands in the droplet.

In the second stage of the PCR procedure, the droplet that contains the amplified target DNA strands are further mixed with other reagents to create analysis spots with different concentrations of DNA [91]. The fluorescence intensities of these analysis spots can be measured to analyze the interaction between probe and target biomolecules.

Despite offering numerous benefits, prior work on PCR implementations on a

FIGURE 4.1: Schematic of a digital microfluidic biochip that can perform DNA amplification [89][93].

digital microfluidic biochip suffers from the following four shortcomings:

1. In all prior work, the functional modules used in the two stages of the PCR procedure are designed separately [89][93], and they cannot be efficiently integrated on the same layout. This mismatch of the two steps often restricts the effectiveness and feasibility of execution of the complete bioassay.
2. The inherent randomness and complexity of bioanalyses are not considered. When a droplet is dispensed into the biochip, there is a probability that the droplet may not contain enough DNA for the PCR (referred to as an “empty droplet”) [94]. The biochips designed in prior work are unable to monitor the presence of empty droplets; hence they cannot terminate the wasteful execution of the PCR.
3. The interferences (electrical, thermal, optical, fluidic) among the devices on the biochip, which arise because of proximity effects, are not considered in previous work. For example, high temperature around the heater may lead to degeneration of a biological sample in a reservoir [95]; therefore, the heater and the reservoir cannot be placed too close to each other.

4. The previously designed PCR biochips are oblivious to the schedule of mixing operations [91]. This may lead to excessive transportation of droplets during mixing/dilution/detection operations in the second stage of the PCR procedure; hence the performance and speed of the biochip may be adversely affected.

To overcome the above shortcomings, we propose the first design method that can optimize the PCR procedure. The key contributions of this chapter are as follows:

1. To overcome the empty-droplet recognition problem, a statistical model for DNA amplification is used to predict whether the droplet has enough DNA strands to carry out the PCR. The intensity of fluorescence detected by the photodetectors (PDs) are fed back to the system on-line, in order to decide whether or not the thermal cycles are to be continued. This helps us to design an efficient cyberphysical PCR biochip on a digital microfluidic biochip platform.
2. We propose a layout design algorithm that considers the interferences among the on-chip elements such as reservoirs, sensors and thermal units. A heuristic algorithm is developed to minimize the area and electrode count of the biochip and satisfy the proximity constraints.
3. The placement of modules considers the time cost of droplet transportation and defect tolerance of the PCR biochip. The overall mixing/dilution/detection time for a given bioassay is optimized, and a droplet-routing method is developed to bypass electrode defects.

This chapter is organized as follows. Section 4.2 describes the statistical model for the amplification of DNA strands and the on-line decision making method during

an actual experiment. Section 4.3 presents the layout design algorithm with the consideration of device interferences. It also describes an application-specific reservoir allocation method. Simulation results for three widely used bioassays are presented in Section 4.4. Section 4.5 concludes this chapter.

## 4.2 Cyberphysical biochip with on-line decision making

Figure 2.5 presents the setup for cyberphysical PCR biochip [96]. The sensing system on biochip monitors the intensity of fluorescence in the droplet, and provides input to the control software. In this way, the software can control the execution of the PCR procedure based on the sensor feedback.

### 4.2.1 Statistical model for the number of DNA strands in a droplet

When droplets are dispensed from the reservoir into the digital microfluidic biochip, the number of DNA strands contained in a droplet can be considered to be a random variable [94][97]. Based on the statistical data derived from several biochemistry experiments, we note that the dispensing process follows Poisson statistics when the density of the DNA strands in the biological sample is low. Therefore, the number of DNA strands in a droplet is given by [94][97]:

$$P(X_c = k) \approx e^{-\lambda} \frac{\lambda^k}{k!} \quad (4.1)$$

where  $k$  is the number of DNA strands in the droplet and  $\lambda$  is the average number of DNA strands per droplet.

When the number of DNA strands in a droplet is too low, the PCR procedure cannot be carried out successfully [98]. The droplets that contain low amounts of DNA strands are referred to as “empty droplets”. If empty droplets are detected at the end of the PCR, the time spent on running the thermal cycles is wasted. In order to investigate this problem, the feedback signal from the integrated sensors can be

used for making an online probabilistic decision whether or not a droplet is empty. As noted in [91][93], during the execution of the PCR, the intensity of fluorescence in the droplets can be monitored by on-chip detectors. If the probability that “the droplet is empty” is high, the droplet will be discarded. A new droplet will then be dispensed into the biochip for PCR processing.

In the next part of this section, we introduce statistical models of the PCR bioassay based on which an on-line decision making system will be designed.

#### 4.2.2 A simplified statistical model for amplification of DNA

During the calibration of the dispensing operation, the probability of generating a “good droplet” can be derived [94]. A good droplet is one that contains a sufficient number DNA strands for running the PCR. Let  $G$  denote the event “a good droplet is dispensed into the biochip”. The complement of  $G$  is the event  $G^c$ , i.e., “an empty droplet is dispensed into the biochip”.

We assume that when running the PCR on a good droplet, the probability of detecting a fluorescence signal (which indicates that the DNA has been amplified) at the  $i^{th}$  thermal cycle is  $p_i$ . Let  $A_k$  denote the event “no signal is obtained from the droplet at the  $k^{th}$  thermal cycle”. Therefore, the joint probability of  $G$  and  $A_k$  can be written as:

$$P(G \cap A_k) = \prod_{i=1}^k (1 - p_i) \cdot P(G) \quad (4.2)$$

If no signal is detected at the  $k^{th}$  thermal cycle, the conditional probability that “this is a good droplet” (written as  $P(G | A_k)$ ) is defined as the quotient of the joint probability of  $G$  and  $A_k$ , and the probability of  $A_k$ :

$$\begin{aligned} P(G | A_k) &= \frac{P(G \cap A_k)}{P(A_k)} \\ &= \frac{P(G \cap A_k)}{P(G \cap A_k) + P(G^c \cap A_k)} \end{aligned} \quad (4.3)$$

where  $P(G \cap A_k) = \prod_{i=1}^k (1 - p_i) \cdot P(G)$ , and  $P(G^c \cap A_k) = P(G^c) = 1 - P(G)$ .

Therefore, we have:

$$P(G \mid A_k) = \frac{\prod_{i=1}^k (1 - p_i) \cdot P(G)}{\prod_{i=1}^k (1 - p_i) \cdot P(G) + 1 - P(G)}$$

$$P(G^c \mid A_k) = \frac{1 - P(G)}{\prod_{i=1}^k (1 - p_i) \cdot P(G) + 1 - P(G)}.$$

#### 4.2.3 An improved statistical model for amplification of DNA

During the calibration of DNA amplification, one may categorize the droplets based on the number of DNA strands therein. Equation (4.3) remains valid in this scenario.

Let event  $G_i$  denote “a droplet with  $i$  DNA strands is dispensed into the biochip”. We assume that  $M_{\min}$  is the minimum number of DNA strands in a droplet needed to run DNA amplification successfully. Then the event  $G$  in Equation (4.3) can be written as:

$$G = G_{M_{\min}} \cup G_{M_{\min}+1} \cup G_{M_{\min}+2} \cup \cdots \cup G_{\infty}, \quad (4.4)$$

where the events  $G_{M_{\min}}, G_{M_{\min}+1}, \cdots, G_{\infty}$  are mutually exclusive.

The event  $A_k$  in Equation (4.3) can now be written as:

$$A_k = A_k^0 \cup A_k^1 \cup A_k^2 \cup \cdots \cup A_k^j \cup \cdots \cup A_k^{\infty}, \quad (4.5)$$

where  $A_k^j$  is the event that “no signal has been observed from a good droplet with  $j$  DNA strands ( $j \geq M_{\min}$ ) after  $k$  thermal cycles”. It is easy to note that the events  $A_k^0, A_k^1, \cdots, A_k^{\infty}$  are mutually exclusive.

From the definitions of  $G_i$  and  $A_k^j$ , it follows that  $P(G_i \cap A_k^j) = 0$ , if  $i \neq j$  or  $i = j < M_{\min}$ . When  $i = j \geq M_{\min}$ , the value of  $P(G_j \cap A_k^j)$  can be empirically derived by calibrating the amplification of DNA. The probabilities  $P(G \cap A_k)$  and

$P(G^c \cap A_k)$  in Equation (4.3) can be calculated as follows:

$$\begin{aligned}
P(G \cap A_k) &= P(G \cap (A_k^0 \cup A_k^1 \cup A_k^2 \cup \dots \cup A_k^j \dots \cup A_k^M)) \\
&= P(G_{M_{\min}} \cap A_k^{M_{\min}}) + P(G_{M_{\min}+1} \cap A_k^{M_{\min}+1}) + \\
&\quad P(G_{M_{\min}+2} \cap A_k^{M_{\min}+2}) + \dots + P(G_{\infty} \cap A_k^{\infty}) \\
P(G^c \cap A_k) &= P(G_0) + \dots + P(G_{M_{\min}-1}).
\end{aligned}$$

When we run DNA amplification on a good droplet that contains  $m$  ( $m \geq M_{\min}$ ) DNA strands, we assume that the probability of detecting the fluorescence signal (i.e., the DNA has been amplified) is  $p_i^m$  at the  $i^{th}$  thermal cycle. Then the value of  $P(G \cap A_k)$  and  $P(G^c \cap A_k)$  can be derived in terms of  $p_i^m$ . Therefore, if the fluorescence signal is not detected at the  $k^{th}$  thermal cycle, the conditional probability that “the droplet is an empty droplet” as well as “the droplet is a good droplet” can be analyzed in a similar way as the method presented in Section 4.2.2.

During DNA amplification on a cyberphysical PCR biochip, the control software calculates the values of  $P(G \cap A_k)$  and  $P(G^c \cap A_k)$  according to the feedback from the sensor at each thermal cycle. When the value of  $P(G^c \cap A_k)$  reaches a threshold value (e.g., 95%), the control software will conclude that the droplet is empty. It will initiate a new set of electrode-actuation sequences to discard the empty droplet and dispense a new droplet into the biochip. The PCR procedure will therefore be continued in an adaptive manner on the biochip.

### 4.3 Optimized layout design under proximity constraints

In this section, we present our algorithm for optimizing the layout under design constraints. On the PCR biochip, there are three categories of devices: reservoirs, PDs, and one thermal unit (e.g., a heater). In order to avoid interferences among the on-chip devices, we assume that the following constraints indicating the minimum (threshold) intra-pair and inter-pair separation distances between the respective device pairs, must be satisfied. These constants are provided as inputs to biochip

designers.

*Separation constraints:*

1. Reservoir to reservoir separation: In order to avoid fluidic leakage between two reservoirs, the distance between them should be no less than a threshold  $L_{RR}$  [99]. A typical value of  $L_{RR}$  is four times the length of electrodes on the digital microfluidic biochip [100].
2. PD to PD separation: Two PDs may have undesirable crosstalk if the distance between them is too short [101]. Therefore, the distance between two PDs should be no less than a minimum value of  $L_{PP}$ . A typical value of  $L_{PP}$  is four times the length of electrodes on the digital microfluidic biochip [27].
3. Reservoir to PD separation: Fluids loaded in the reservoirs may contain fluorescent labels and thus they may influence the accuracy of a PD [99]. Therefore, the separation between a reservoir and a PD should be no less than a threshold  $L_{RP}$ . A typical value of  $L_{RP}$  is five times the length of electrodes on the digital microfluidic biochip [27].
4. Reservoir to heater separation: Since the biological samples and reagents loaded in the reservoirs may undergo degeneration under heating [95], the distance between a reservoir and a heater should be no less than a threshold  $L_{RH}$ . A typical value of  $L_{RH}$  is five times the length of electrodes on the digital microfluidic biochip [89].
5. PD to heater separation: A proximity to a heater may affect the sensitivity of a PD [102]. Hence, the distance between a PD and a heater should be no less than a minimum value of  $L_{PH}$ . A typical value of  $L_{PH}$  is three times the length of electrodes on the digital microfluidic biochip [89].

For simplicity, we define an operator  $\mathcal{C}$ , which is a mapping from a pair of arbitrarily chosen devices (written as  $d_a$  and  $d_b$ ) to the required minimum distance

between them:

$$\mathcal{C} : (d_a, d_b) \rightarrow \text{Minimum distance between } d_a \text{ and } d_b.$$

For example, if  $d_a$  denotes a PD and  $d_b$  denotes a heater, then  $\mathcal{C}(d_a, d_b) = L_{\text{PH}}$ .

In order to design the layout for a PCR biochip with devices  $d_{1 \sim n}$  on it, we must determine the coordinates of all the devices (written as  $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ ), such that:

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \geq \mathcal{C}(d_i, d_j), \quad \forall i, j.$$

#### 4.3.1 Resource placement on PCR biochips

We assume that the PCR layout will be built on an underlying 2D unit square lattice, where each grid point has integer Cartesian coordinates. Every physical device/electrode is assumed to be placed around a grid point. If  $d_a$  and  $d_b$  denote two devices to be placed on the chip, we draw two circles each with radius  $\frac{\mathcal{C}(d_a, d_b)}{2}$ , centering at  $d_a$  and  $d_b$ . If these two disks are disjoint, i.e., non-overlapping, then the distance between their centers will be no less than  $\mathcal{C}(d_a, d_b)$ . In other words, the corresponding separation constraint will be satisfied. However, in order to minimize the area of the chip, all the devices need to be placed as closely as possible. An example of compact placement of a heater and a reservoir is shown in Figure 4.2(a). The problem for determining such a compact non-overlapping placement is similar to the widely-studied problem of “circle packing” in the Euclidean space, and is defined as follows [103]:

**Definition 1.** “A circle packing is a configuration  $P$  of circles realizing a specified pattern of tangencies.”

However, the device placement problem in a biochip differs from the classical circle packing in the following two aspects: (i) The layout of a digital microfluidic biochip consists of a discrete electrode array; hence the devices (which are represented by the centers of the corresponding circles needed to be packed) are constrained to

(a)

(b)

FIGURE 4.2: (a) Compact placement of a reservoir and a heater; (b) outer isothetic cover (OIC) that tightly encloses the forbidden region of  $R_2$ ; optimal placement of a reservoir  $R_2$  in the presence of a reservoir  $R_1$ , a PD  $P_1$ , and a heater  $H$ .

lie on integer grid points, and (ii) for two devices  $d_a$  and  $d_b$ , the radius of the circle  $\frac{\mathcal{C}(d_a, d_b)}{2}$ , depends on the device pair. Therefore, the definition of “tangency of two circles” should be modified as follows.

**Definition 2.** *The circles centered at the locations of  $d_a$  and  $d_b$  are tangent to each other if the distance between their centers is exactly equal to  $\mathcal{C}(d_a, d_b)$ .*

Since every pair of devices may require a distinct separation constraint, the overall search space may become very large and we conjecture that the problem of finding a minimum-area layout is an non-deterministic polynomial-time hard problem [104]. Hence to build our design tool, we use the following greedy algorithm based on an iterative method.

Let us assume that some devices are already placed while satisfying their mutual separation constraints, and a new device is now to be placed on the chip. In order to

satisfy its proximity constraints with each of the other devices, we reformulate the circle packing approach by defining a forbidden region for each existing device with respect to the current one. Thus if  $d_i$  denotes an existing device and  $d_j$  denotes a new device, a forbidden region where  $d_j$  cannot be placed will be inside the circle of radius  $\mathcal{C}(d_i, d_j)$  centered at  $d_i$ . The boundary of the overall forbidden region, at any instant of time, will then be defined by a set of circular arcs whose centers denote the locations of the devices already placed on the chip. The radius of a circle is determined by the required minimum distance between the corresponding device and the new one.

In our iterative method, first we choose one device  $d_i$  and place it at the origin  $(0,0)$  of the layout grid. Next, another device, say  $d_j$  is chosen for placement. We draw a circle of radius  $\mathcal{C}(d_i, d_j)$  with its center at  $d_i$ . We flag all the grid points which lie inside the circle as “forbidden” while placing  $d_j$ . Thus  $d_j$  may be placed on any grid point that lies on or outside the circle to satisfy the separation constraint. At any instant of time, let us assume that the devices  $d_1, d_2, \dots, d_k$  have already been placed. When considering the placement of the device  $d_{k+1}$ , we proceed as follows: for each device  $d_i$  already placed, we draw a forbidden circle centering at  $d_i$  with radius  $\mathcal{C}(d_i, d_{k+1})$ , and flag all the grid points as “forbidden” that lie in the interior of the union of all these circles. The point  $d_{k+1}$  may be placed anywhere outside this forbidden region. However, to minimize the layout area, we place it on a grid point such that the area of the convex hull [105] of the point set  $\{d_1, d_2, \dots, d_k, d_{k+1}\}$  is minimized. This procedure is illustrated in Figure 4.2(b), where in the presence of a heater  $H$ , a PD  $P_1$ , and a reservoir  $R_1$ , we show how a new reservoir  $R_2$  can be optimally placed. We also assume that the heater is placed at the origin of the layout in the first step of our algorithm.

In each subsequent iteration, we randomly choose a device whose position has not been determined. The device will be optimally placed by the above algorithm.

In order to manipulate the forbidden region efficiently while implementing our algorithm, we use the concept of “outer isothetic cover (OIC)” of a digital contour

[106]. The OIC is a tight-fitting axis-parallel polygon that just encloses a given contour on a 2D grid. In our case, the contour is defined by a set of circular arcs (see Figure 4.2(b)). Hence all the grid points that are labeled as forbidden will be in the interior of the OIC, and all other grid points will be on its boundary or outside. Since our objective is to minimize the layout area, it is sufficient to limit the search for possible placements of a new device only to the set of grid points that lie on the boundary of the OIC. Let  $L_{max}$  denote the maximum value of all the separation thresholds (i.e., maximum radius of a forbidden circle). Since  $L_{max}$  is a constant, the number of grid points on the boundary of OIC when  $k$  devices are already placed, will be  $O(k)$ . Clearly, any grid point chosen on the boundary of the OIC will satisfy all the separation constraints for placing the next device  $d_{k+1}$ . Thus, instead of explicitly flagging all the  $O(k^2)$  forbidden grid points lying at the interior of the circles, we mark only  $O(k)$  valid grid points on the boundary of the OIC. During the execution of our algorithm, for the  $k$  devices which are already placed, we maintain a convex hull on the set of grid points corresponding to their locations. Next, while placing the device  $d_{k+1}$ , we search among the grid points on the boundary of the OIC, such that the area of the incremental convex hull is minimized. This can be found in  $O(k^2 \log k)$  time, since for each point on the boundary OIC, the new convex hull can be computed in  $O(k \log k)$  time [105]. Hence the total time complexity of placing  $n$  devices on the PCR biochip will be  $O(n^3 \log n)$ . An improved algorithm can be designed by using a more sophisticated data structure used for dynamic maintenance of a convex hull [107].

In our heuristic algorithm, we have chosen the ordering of device placement randomly, and this ordering may influence the layout area. Assume that we have  $N_r$  indistinguishable reservoirs, and  $N_d$  indistinguishable PDs, and  $N_h$  heaters. Thus the number of possible orderings of device placement is given by

$$\frac{(N_r + N_d + N_h)!}{N_r! N_d! N_h!}.$$

In practice, only a few PDs are integrated on a biochip due to their high fabri-

cation cost, and a single heating/cooling module suffices. The number of reagents required in a typical mixing procedure after DNA amplification is around 8. Also, it is customary to place the output ports of reservoirs around the boundary of the chip and the heater in the interior. Therefore, the number of possible orderings significantly reduces in a practical scenario. Hence we have run the above-mentioned heuristic algorithm exhaustively on all orderings. The one that yields the minimum area of the biochip is selected. In the next subsection, we will discuss how to optimize droplet transportation and mixing time in the context of a specific bioassay protocol.

#### 4.3.2 *Bioassay-specific reservoir allocation for PCR biochips*

The placement algorithm described in the previous section assigns a location for each of the devices on a 2D grid. To complete the layout design, we now have to create the droplet transportation paths among the devices. In a typical mixing procedure after DNA amplification, several reagents/samples are required to be mixed in a certain ratio. The number of mix-split operations depends on the mixing algorithm and the target ratio. The mixing process is generally represented as a mixing (or a sequencing) graph  $G$ , where each leaf node represents a reagent and an internal node represents a fluidic operation, e.g., mixing/splitting [74]. Hence, the droplet transportation cost in the PCR should be optimized based on the given mixing ratio. This needs appropriate allocation of reservoirs to the reagents and scheduling of mixing/dilution/detection operations as specified in the sequencing graph.

In order to reduce the number of electrodes on the biochip, we do not pre-assign any specific region for mixer modules. We assume that all the mixing/splitting operations will be performed on the electrodes lying between the output ports of reservoirs. Let  $D_1$  and  $D_2$  denote two dispensing operations from reservoirs  $R_1$  and  $R_2$  respectively, and let  $M_1$  represent a mixing operation between these two droplets (Figure 4.3(a)). A possible placement of these modules is shown in Figure 4.3(b). The droplets dispensed from  $R_1$  and  $R_2$  are mixed on the electrode array between these two reservoirs.

Given a specific reservoir allocation to the reagents, the droplet transportation

FIGURE 4.3: (a) Sequencing graph for the dispensing and mixing of two droplets; (b) placement of the output port of reservoirs and the mixer; (c) an example of defect tolerance by droplet rerouting.

cost for the entire bioassay can be estimated from the sequencing graph as follows:

**Step 1:** Assign a physical location to each node in the sequencing graph  $G$ . For a node  $N_{ar}$  in  $G$ , we may have the following cases:

1. If  $N_{ar}$  represents a dispensing operation, then the coordinates of  $N_{ar}$  are set as those of the corresponding reservoir.
2. If  $N_{ar}$  represents a mixing/splitting operation between two nodes  $N_1$  and  $N_2$ , then the coordinates of  $N_{ar}$  are set as:

$$x_{N_{ar}} = \frac{x_{N_1} + x_{N_2}}{2} \text{ and } y_{N_{ar}} = \frac{y_{N_1} + y_{N_2}}{2},$$

where  $(x_{N_1}, y_{N_1})$  and  $(x_{N_2}, y_{N_2})$  are the coordinates assigned to nodes  $N_1$  and  $N_2$ , respectively.

**Step 2:** Estimate the cost of droplet transportation for each node in the sequencing graph  $G$ . For a node  $N_{ar}$ , we may have the following two cases:

1. If  $N_{ar}$  represents a dispensing operation, then the cost of droplet transportation for  $N_{ar}$  is set to zero.
2. If  $N_{ar}$  represents a mixing/splitting operation between two nodes  $N_1$  and  $N_2$ , then the cost of droplet transportation for  $N_{ar}$  (written as  $T_{N_{ar}}$ ) is set as the Manhattan distance between the two nodes:

$$T_{N_{ar}} = |x_{N_1} - x_{N_2}| + |y_{N_1} - y_{N_2}|,$$

where  $(x_{N_1}, y_{N_1})$  and  $(x_{N_2}, y_{N_2})$  are the coordinates of nodes  $N_1$  and  $N_2$ , respectively.

**Step 3:** Estimate the cost of droplet transportation for detection operation. We assume that a droplet corresponding to a node  $N_{ar}$  will be sent to the nearest PD for optical detection (the corresponding detection operation is represented as  $D_{N_{ar}}$ ); then the cost of droplet transportation for  $D_{N_{ar}}$  is set as:

$$D_{N_{ar}} = \min(|x_{N_{ar}} - x_{d_1}| + |y_{N_{ar}} - y_{d_1}|, |x_{N_{ar}} - x_{d_2}| + |y_{N_{ar}} - y_{d_2}|, \dots, |x_{N_{ar}} - x_{d_{N_d}}| + |y_{N_{ar}} - y_{d_{N_d}}|),$$

where  $(x_{d_1}, y_{d_1}), (x_{d_2}, y_{d_2}), \dots, (x_{d_{N_d}}, y_{d_{N_d}})$  are the corresponding coordinates for the  $N_d$  PDs on the layout.

**Step 4:** For each possible configuration of reservoir allocation, the overall droplet transportation time for the bioassay is estimated by adding the transportation costs of all the operations in the mixing procedure. The one with the minimum droplet transportation time is selected for reservoir allocation.

#### 4.3.3 Layout design of PCR biochips

Once the reservoir allocation step is completed, we establish droplet transportation pathways to connect these reservoirs based on the sequencing tree. A device or a mixing module is assigned to each node of the tree based on their coordinates attached to it. As mentioned in Section 4.3.1, a heater is placed at the origin of the layout. Typically, all the output ports of reservoirs on the layout are connected in a “cycle” consisting of electrodes [68][93]. The defect tolerance of PCR biochips with this circular electrode path can be enhanced. An example is shown in Figure 4.3(c). Two droplets are scheduled to be mixed together, and their original transportation paths are indicated by the arrows. When a defect is present on the layout, the transportation paths of these two droplets can be dynamically adjusted. Therefore, by using an alternative droplet transportation path, the PCR biochip can be used despite the presence of the defect.

- 1: **Phase 1:**
  - 2: **for** each permutation of  $n$  devices (written as  $\{d_{k_1}, d_{k_2}, \dots, d_{k_n}\}$ ) to be placed on the layout **do**
  - 3:   Place  $d_{k_1}$  at the origin of the layout;
  - 4:   **for** each  $d_{k_i} \in \{d_{k_2}, d_{k_3}, \dots, d_{k_n}\}$  **do**
  - 5:     Draw the forbidden circular regions constrained by each of the devices  $\{d_{k_1}, d_{k_2}, \dots, d_{k_{i-1}}\}$  with respect to  $d_{k_i}$ . Construct the OIC enclosing the forbidden regions;
  - 6:     Find the grid point  $g_i$  on the boundary of the OIC, such that area of the convex hull defined by the points located at  $\{d_{k_1}, d_{k_2}, \dots, d_{k_i}\}$  is minimum. Place the device  $d_{k_i}$  on  $g_i$ ;
  - 7:   **end for**
  - 8:   Output the placement geometry and calculate the area of the biochip;
  - 9: **end for**
  - 10: Choose the least-area device placement; // At this step, the locations of all the devices are determined. All the reservoirs are considered identical.
  - 11: **Phase 2:**
  - 12: Determine the best reservoir allocation of reagents based on the estimated time cost of droplet transportation and the frequency of reactant usage;
  - 13: Establish routing paths to connect all the devices following the sequencing tree;
- 

FIGURE 4.4: Pseudocode for layout design for PCR biochips.

Finally, the paths consisting of electrodes are added in order to connect the PDs to the respective mixer nodes. The pseudocode for the entire design cycle is shown in Figure 4.4.

## 4.4 Simulation results

In this section, we first present simulation results to evaluate the proposed methodology for designing a cyberphysical and layout-aware PCR biochip for a specific bioassay. We also present simulation results on three benchmarks for mixing protocols.

### 4.4.1 Probabilistic approach to control DNA amplification on a biochip

The statistical model proposed in Section 4.2.1 can be used for on-line decision making during the amplification of DNA strands. It is important to note that the fluorescence signal from the amplified DNA may not be detected immediately when the target DNA strands are amplified. This is because of the fact that each PD has a minimum detectable signal (MDS) [108]. The fluorescence signal of the amplified DNA cannot be detected if its strength is lower than the MDS. Therefore, in our statistical model, we assume that, when we perform thermal cycles on a droplet, the

FIGURE 4.5: Relationships between  $i$  (i.e., the number of thermal cycles that have been carried out) and  $P(G^c|A_i)$  (i.e., the probability that “this droplet is an empty droplet”) derived using three statistical models of PCR procedure.

probability of detecting a fluorescence signal from the amplified DNA strands is zero before the  $N^{th}$  thermal cycle. At the  $i^{th}$  ( $i \geq N$ ) thermal cycle, the probability of detecting the fluorescence signal (i.e., the DNA is amplified) is  $p_i$ .

If we assume that  $N = 20$ ,  $P(G) = 0.8$ , and  $p_i = 0.3$  ( $\forall i \geq 20$ ). The relationship between  $i$  (i.e., the number of thermal cycles that have been carried out) and  $P(G^c|A_i)$  (i.e., the probability that “this droplet is an empty droplet”) is shown in Figure 4.5(a). From Figure 4.5(a), we observe that, if there is no sensor signal at the  $25^{th}$ ,  $27^{th}$ , or  $28^{th}$  thermal cycles, the value of  $P(G^c|A_i)$  is 85%, 90%, or 95%, respectively. The relationship between  $i$  and  $P(G^c|A_i)$  when setting “ $P(G) = 0.8$  and  $p_i = 0.2$ ”, and “ $P(G) = 0.7$  and  $p_i = 0.3$ ” can also be found in Figure 4.5(a).

Since there is an exponential increase in the number of target DNA strands

when the PCR is performed successively, we can also assume that the probability  $p_i$  increases exponentially. For example, we can set  $N = 20$ ,  $P(G) = 0.8$ , and set  $p_i$  as follows:

$$p_i = \begin{cases} 0, & \text{if } i < N \\ p^* \times 2^{i-N}, & \text{if } N \leq i \leq N - \log_2 p^* \\ 1, & \text{if } N - \log_2 p^* < i \end{cases}$$

In this scenario, the corresponding relationship between  $P(G^c|A_i)$  and  $i$  is shown in Figure 4.5(b). In the three curves shown in Figure 4.5(b), the value of  $p^*$  is set as  $10^{-4}$ ,  $10^{-5}$ , and  $10^{-6}$ , respectively. For example, when  $p^*$  is set as  $10^{-5}$ , from the figure we can conclude that if there is no signal at the 36<sup>th</sup> thermal cycle, the probability that “this droplet is an empty droplet” is 60%; if there is no signal at the 37<sup>th</sup> thermal cycle, the probability becomes 99%. Therefore, if no signal is detected after the 37<sup>th</sup> thermal cycle, we have a 99% confidence level that the droplet does not contain enough DNA strands for PCR, and the droplet should be discarded.

We can also analyze the stage of DNA amplification by considering the more detailed statistical model introduced in Section 4.2.3. Since in the ideal case, the number of DNA strands in a droplet increases exponentially, we assume that the value of  $p_i^m$  can be written as follows:

$$p_i^m = \begin{cases} 0, & \text{if } i < N \\ p' \times m^{i-N}, & \text{if } N \leq i \leq N - \log_2 p' \\ 1, & \text{if } N - \log_2 p' < i \end{cases}$$

where  $M_{\min} = 3$  and  $N = 20$ . For the distribution of the number of DNA strands in droplets shown in Equation (4.1), we assume that  $\lambda = 4$ . The relationships between  $i$  and  $P(G | A_i)$  when the value of  $p'$  is set as  $10^{-4}$ ,  $10^{-5}$ , and  $10^{-6}$ , are shown in Figure 4.5(c).

#### 4.4.2 Layout design for PCR biochips

Consider a biochip with seven reservoirs, two PDs, and one heater; the separation constraints are set as  $L_{RR} = 4$ ,  $L_{PP} = 4$ ,  $L_{RP} = 5$ ,  $L_{RH} = 5$ , and  $L_{PH} = 3$ . The

FIGURE 4.6: (a) Device placement obtained by the proposed algorithm.  $R$  represents the output port of the reservoir,  $P$  represents the PD, and  $H$  represents the heater. All the reservoirs are treated as identical devices and all the PDs are treated as identical devices; (b) Reservoir allocation with the minimum droplet routing cost.  $R_{1\sim7}$  are reservoirs assigned to inputs  $x_{1\sim7}$  in Figure 4.7,  $P_1$  and  $P_2$  are PDs, and  $H$  is the heater. The white squares correspond to electrodes.

FIGURE 4.7: Sequencing graph for a solution preparation procedure. The inputs of the mixing procedure are seven different kinds of samples/reagents and the final output is the droplet that has the mixing ratio of 2:3:5:7:11:13:87 [74]. These seven samples/reagents are loaded into reservoirs  $R_{1\sim7}$  on the PCR biochip.

simulation is run on a 2.30 GHz Intel i3 dual-core processor with 8 GB of memory. The CPU time needed to generate all the possible device placements is 92.0 seconds. One of these layout designs with the minimum area is shown in Figure 4.6(a). The output ports of reservoirs, PDs, and the heater are represented by “ $R$ ”, “ $P$ ”, and “ $H$ ”, respectively. If each electrode is assumed to have unity area, the size of the smallest-area rectangle enclosing the layout turns out to be  $14 \times 10$ .

After we design a layout with the minimum area, a suitable reservoir allocation for reducing droplet transportation is determined based on the protocol of a specific PCR. Figure 4.7 shows a mixing procedure for solution preparation, which is referred as Bioassay 1 [74]. Let us assume that reagent  $x_6$  contains the amplified DNA strands obtained from the first stage of PCR, and output droplets of the mixing operations  $M_2$ ,  $M_6$ ,  $M_{10}$ , and  $M_{13}$  will be detected by the PDs. According to the frequency of reactant usage in the mixing procedure, the optimal result of reservoir allocation can be derived by the heuristic algorithm proposed in Section 4.3.2. Figure 4.6(b) shows the final layout obtained after reservoir allocation that minimize droplet transportation time. Reagents  $x_{1\sim 7}$  in Figure 4.7 are loaded into  $R_{1\sim 7}$ . The CPU time needed to compute this result of reservoir allocation is 0.4 second and the number of electrodes on the layout is 45. It is important to note that, the heater is used to create a high temperature zone on the layout and it will not be connected with other devices.

While executing the bioassay, the electrode path that connects the output ports for a pair of reservoirs can be assigned as mixers. All the mixing operation in the protocol can thus be performed “locally” without long-distance transportation or conflicts in droplet routing. For example, the inputs of operations  $M_1$ ,  $M_4$ , and  $M_8$  are reagents  $x_4$  and  $x_7$ , and accordingly, these mixing operations will be performed on the electrodes between  $R_4$  and  $R_7$ .

In addition, since the conflicts of resource-sharing and droplet routing on the biochip can be avoided, the degree of parallelism for fluid-handling operation is high.

We assume that the completion time of mixing on a  $1 \times 4$  mixer is 5 seconds, and the time to move the droplet from electrode to another electrode is  $t_m$  second ( $t_m$

FIGURE 4.8: (a) The result of device placement derived by the baseline algorithm. The output ports of reservoir 1 ~ 7, PD 1 ~ 2 and the heater are placed on the boundary of the layout one by one.  $R_1$  and  $R_2$  here represent the output ports of two reservoirs; (b) conflicts of droplet routing on the layout derived by the baseline algorithm.

usually varies from 0.01 to 1 [21]). Then the execution time of the whole bioassay on the layout shown in Figure 4.6(b) will be  $(35+16t_m)$  seconds.

Here we design another device placement as the baseline algorithm. In the baseline method, all the devices (including the output ports of reservoirs, PDs, and the heater) are placed at the boundary of the layout one by one. The distance between any two devices is set as  $L_{max} = \max\{L_{RR}, L_{PP}, L_{RP}, L_{RH}, L_{PH}\}$ , as shown in Figure 4.8. A circular path, which consists of all the boundary electrodes, connects all these devices.

The size of the electrode array derived by baseline algorithm is  $17 \times 17$ , and the number of electrodes required for this design is 64. When we execute the mixing bioassay on the layout derived by the baseline algorithm, conflicts in droplet routing and resource sharing may occur. An example is shown in Figure 4.8(b). As defined by the sequencing graph shown in Figure 4.7, the droplets dispensed from  $R_1$  and  $R_4$  need to be mixed together in  $M_5$ , and the droplets dispensed from  $R_3$  and  $R_5$  need to be mixed together in  $M_3$ . The transportation paths of the droplets dispensed from  $R_1$ ,  $R_3$ ,  $R_4$ , and  $R_5$  are indicated by the arrows in Figure 4.8(b).

Table 4.1: Comparison of the PCR biochips derived by proposed method and the baseline algorithm.

Bioassay	Mixing ratio	Proposed method			Baseline algorithm		
		Size of the biochip	No. electrodes	Execution time (s)	Size of the biochip	No. electrodes	Execution time (s)
1	2 : 3 : 5 : 7 : 11 : 13 : 87 [74]	14 × 10	45	35 + 16 <i>t<sub>m</sub></i> (36.6)*	17 × 17	64	55 + 36 <i>t<sub>m</sub></i> (58.6)*
2	10% : 10% : 8% : 0.8% : 0.8% : 1% : 68.4% : 1% [109]	14 × 11	46	60 + 32 <i>t<sub>m</sub></i> (63.2)	18 × 18	68	90 + 56 <i>t<sub>m</sub></i> (95.6)
3	7 : 14 : 11 [58]	11 × 7	30	25 + 12 <i>t<sub>m</sub></i> (26.2)	12 × 12	44	25 + 25 <i>t<sub>m</sub></i> (27.5)

\* Numbers in parenthesis indicate execution time for  $t_m = 0.1$ .

It is easy to observe that the mixing operations  $M_3$  and  $M_5$  cannot be executed concurrently. The execution time of the complete bioassay on the layout shown in Figure 4.6(b) will be  $(55+36t_m)$  seconds.

Compared with the baseline algorithm, the proposed design method can thus reduce the chip area by 52%, the number of electrodes by 27%, and the execution time by 38% (when the value of  $t_m$  is set as 0.1).

Next, we study a protocol, which represents a real-life PCR mixing ratio [109]. This bioassay is referred to as Bioassay 2. The mixing ratio of the eight components is written as [109]:

{Reaction buffer: Mag\_Sulf: dNTPs: Forward primer: Reverse Primer: Optimase: Water: DNA} = {10% : 10% : 8% : 0.8% : 0.8% : 1% : 68.4% : 1%}. The corresponding mixing tree can be derived by the ratioed mixing algorithm (RMA) [74]. The simulation results of the PCR biochip designed for Bioassay 2 are shown in Table 4.1.

We consider another mixing protocol called Bioassay 3 [58], which has three input reagents/samples. The results are shown in Table 4.1. In all the three cases, the layout size, electrode count, and execution time of bioassays are significantly improved compared to the baseline method.

#### 4.4.3 Defect tolerance of layouts for PCR biochips

Because of manufacturing imperfections and degradation of electrodes, physical defects may occur on digital microfluidic biochips. The defects can be classified into two categories based on their locations on the biochip. If a defect disconnects a droplet path into two “isolated parts” (i.e., droplets cannot be moved from one part to the other part), it is defined as a “catastrophic defect”. All other defects are defined as “non-catastrophic defects”.

If a catastrophic defect occurs, the PCR biochip cannot be used further. On the layout designed for Bioassay 1, the positions of electrodes where defects are catastrophic are shown in Figure 4.9(a). For each of these three PCR biochips designed

FIGURE 4.9: (a) The positions of “catastrophic defects”. If the electrodes at these positions have defects, the biochip cannot be used any more; (b) non-catastrophic defect can be by-passed by adjusting the routing of droplets.

Table 4.2: Defect tolerance of PCR biochips.

Bioassay	Total number of electrodes where defects are catastrophic	Average execution time when a non-catastrophic defect is injected (s)	Standard deviation of execution time when a non-catastrophic defect is injected (s)
1	17	58.7	8.3
2	16	86.8	12.6
3	7	33.9	11.6

for Bioassays 1 ~ 3, the total number of electrodes where defects are catastrophic is shown in Table 4.2.

If a non-catastrophic defect occurs, we can re-route the droplets to send them to their destinations, as shown in Figure 4.9(b). It is important to note that re-routing the droplet may increase the length of the transportation path, and reduce the degree of parallelism of fluid-handling operations. Therefore, compared with the defect-free biochip, the execution time of the bioassay on a biochip with a non-catastrophic defect is higher. Nevertheless, we can achieve defect tolerance through software adaptation.

For each PCR biochip, we randomly insert a non-catastrophic defect into the biochip, and then calculate the execution time of the bioassay. The defect-insertion simulation is exhaustive in that it is executed for all possible non-catastrophic defects on the layout. The average value and the standard deviation for execution time of running bioassays on biochips with defects are shown in Table 4.2. The value of  $t_m$  is

set as 0.1. From the table, we find that the percentage of electrodes where defects are catastrophic is 23.3%~37.8%, i.e., most of the defects can be tolerated by rerouting the droplets. With the presence of a single non-catastrophic defect, the PCR biochip can be used via graceful degradation with a 29.4%~66.4% increase in the execution time of bioassay.

## 4.5 Chapter summary and conclusions

In this chapter, we have shown how the cyberphysical integration of a PCR protocol on digital microfluidics can be used to reliably execute on-chip bioassays, despite the uncertainties inherent in fluidic operations such as dispensing operation and thermal cycling. The proposed design approach facilitates dynamic on-line decision making for the termination of thermal cycles in response to feedback from sensors. We have also presented new algorithms for device placement and layout design that safeguard the bioassay against undesirable device interferences and reduce the execution time. Simulation results on three laboratory protocols demonstrate that the proposed design method can achieve high reliability and defect-tolerance with minimum chip area and electrode count.

## Biochemistry Synthesis under Completion-Time Uncertainties in Fluidic Operations

### 5.1 Introduction

Digital microfluidics enables the integration of fluid-handling operations, biochemical reaction-outcome detection, and software-based control in a biochip. Biochemical assays, such as the dilution of samples and reagents, crystallization of protein molecules, on-chip chemistry for DNA sequencing, multiplexed real-time polymerase chain reaction (PCR), protein crystallization for drug discovery, and glucose measurement for blood serum, have been successfully implemented on digital microfluidic biochips.

The precision of fluidic operations is vital for the accuracy of analytical bioassays. For example, in the quantitative measurement for glucose concentration in blood [54], accurate measurements cannot be obtained if the mixing time for blood sample and enzymatic reagent is not controlled precisely. In order to determine appropriate parameter settings and increase the precision of on-chip operations, bioassays need to be thoroughly characterized [21; 110; 111], i.e., fluidic operations must be repeatedly executed and monitored to obtain statistically significant results [110]. Based on

these results, a module library is derived to define the execution time for each type of operation, and this library is used as the guideline for the execution of on-chip operations.

However, as the characterization of bioassays requires repeated execution of each operation, it is a time-consuming process and leads to the wastage of sample and reagent droplets. Even after careful characterization, the problem of inaccuracy remains due to the inherent variability and randomness of biological/chemical processes [21; 32; 43; 110; 111; 112]. When a large number of fluidic operations are involved, the bioassay yield is low due to the compounding inaccuracy for multi-step assays. Here the yield of bioassay is defined as the percentage of bioassay instances that can produce outcome droplets with expected concentrations.

In order to overcome the drawbacks associated with characterization, biochips integrated with sensing systems, i.e., cyberphysical microfluidic biochips, are being developed [54][111][113][114]. The feedback provided by the sensing system enables real-time concentration checking, error detection, and error correction for fluidic operations [54]. Therefore, essential operations such as droplet dispensing and mixing can be precisely implemented on cyberphysical microfluidic biochips without the need for characterizing a bioassay or specifying a module library [54][113].

However, today's synthesis algorithms for mapping biochemistry protocols to the chip still rely on characterization procedures for bioassays [51; 64; 115]. Hence the advantages of cyberphysical integration are not fully exploited, and precious samples/reagents and time are wasted during characterization. In addition, current design methods suffer from the following limitations:

1. Prior work is oblivious to variability and uncertainty in biochemical processes.

The competition-time of fluidic operations in practical applications may be different from the time defined in a module library, therefore the accuracy of

fluidic operations cannot be guaranteed.

2. The synthesis results in [51; 64; 115] are not robust when timing uncertainties of operations exist. When the feedback from on-chip sensors indicates that the completion time of an operation is different from the time defined in the module library, the re-synthesis procedure has to be performed. In each re-synthesis procedure, the control software must adjust the schedule and module-placement for a series of operations. These cumbersome on-line computation steps require high CPU time. The resulting response time may interrupt the execution of the bioassay and lead to the degeneration of intermediate products of the bioassay [96].
3. On-line computation in prior work does not generate the information for droplet transportation, which is essential for the execution of a bioassay.

To overcome the above drawbacks, we propose a new design for on-line decision-making using cyberphysical microfluidic biochips. The key contributions and benefits of this work are as follows:

1. We propose the design of microfluidic biochips using multiple clock frequencies. The execution time of the bioassay can be reduced without additional degradation of electrodes or hardware cost.
2. We propose an “operation-interdependence-aware” synthesis algorithm, the first on-chip biochemistry synthesis procedure that does not use the module library as a design guideline. Using this algorithm, the characterization process can be eliminated. The algorithm leads to a design approach that considers completion-time uncertainties for fluidic operations, hence the accuracy of fluidic operations is improved. The proposed approach explicitly considers

the transportation of droplets. Hence it guarantees the feasibility of droplet-routing, and determines the transportation path for each droplet.

3. We propose the on-line droplet-routing method that has low computational complexity. The response time of the cyberphysical system is negligible. Therefore, the degeneration of intermediate products for the bioassay can be avoided.

The remainder of this chapter is organized as follows. Section 5.2 presents the design of microfluidic biochips with multiple clock frequencies. Section 5.3 introduces the framework of operation-dependency-aware synthesis. Based on results derived from the proposed synthesis algorithm, integrated on-line decision-making for droplet transportation path is presented in Section 5.4. Simulation results for three widely used bioassays are presented in Section 5.5. Section 5.6 concludes the chapter.

## 5.2 Biochips with multiple clock frequencies

Experimental results published in the literature demonstrate that the degradation of an electrode is directly related to the number of times that it is switched on and off [116]. With the same sequence of electrode actuation vectors, electrodes will degrade more quickly under higher clock frequency. On the other hand, an increase in the clock frequency can reduce the execution time of fluid-handling operations [21]. Hence, in order to ensure the reliability of electrodes on the biochip, and at the same time complete the bioassay under timing constraints, it is important to choose an appropriate clock frequency.

Fluid-handling operations are divided into two categories: frequency-sensitive operations and frequency-insensitive operations. The completion time of droplet transportation and dispensing is determined by clock frequency, because the droplet will be moved from one electrode to another adjacent electrode in each clock cycle; hence the rate at which a droplet is transported or dispensed is proportional

to the clock frequency. Note that, if the transportation or dispensing path for a droplet consists of  $P$  electrodes, then the number of clock cycles required to move or dispense the droplet is also  $P$ . This number of clock cycles only relates to the length of the transportation path, and it is independent of the clock frequency. If we increase the electrode switching frequency for droplet transposition and dispensing, the time needed for these operations can be reduced without additional degradation of electrodes. Hence, we conclude that by increasing the clock frequency, the transportation and dispensing time of droplets can be accelerated without affecting the chip reliability.

The execution times of mixing and dilution operations cannot be significantly reduced by increasing the clock frequency. For example, experimental results for droplet mixing show that, at a frequency of 8 Hz, the time spent on the mixing operation is 12 seconds; when the frequency is increased to 16 Hz, the mixing time decreases to 11 seconds [21]. Hence the mixing time only decreases 8.3% while the rate of degradation of electrodes increases 100%. Therefore we conclude that increasing the clock frequency for dilution/mixing operation may adversely affect the lifetime of the biochip, while the completion time of the operation will not be significantly reduced.

In order to minimize the time required to complete a bioassay with least impact on chip reliability, it is desirable to run different categories of operations at different clock frequencies. Hence we propose to schedule transportation/dispensing operations and dilution/mixing operations at different time segments. The time segment to implement droplet transportation is defined as the “transportation phase” (T phase), and the segment to implement dilution/mixing operations is defined as the “dilution/mixing phase” (D/M phase); see Figure 5.1(a). For each phase, only transportation operations or the dilution/mixing operations are carried out on the chip.

FIGURE 5.1: (a) Droplet transportation and dilution/mixing operations are scheduled in different phases; (b) start and end time of a D/M phase.

FIGURE 5.2: A tunable frequency-divider controlled by the feedback from sensors.

Assume that we have already determined the set of dilution/mixing operations to be implemented at each D/M phase before the execution of a bioassay. At run-time, the biochip operates under clock frequency  $f_T$  in the T phase. Output droplets of previous steps and droplets dispensed from reservoirs are moved to the modules where the subsequent dilution/mixing operations are to be carried out. After all the droplets arrive at their destination modules, the biochip enters the D/M phase. The dilution/mixing operations that are scheduled in the same phase start together, and they are carried out under clock frequency  $f_{D/M}$ . When the feedback from sensors indicates all the dilution/mixing operations have already been completed, the D/M phase ends and the biochip enters the next T phase, as shown in Figure 5.1(b). In this way, based on sensor feedback, the biochip “switches” between the T phase and

FIGURE 5.3: Sequencing graph with tree structure (a) all edges are directed towards the root of the tree; and (b) all edges are directed away from the root; (c) scheduling results for mixing operations 1, 2, and 6; (d) module-placement for 1, 2 and 6; (e) storage units  $S_1$  and  $S_2$  inside the modules assigned for operations 1 and 2; (f) packaged macro-operations  $M_{S_L}$  and  $M_{S_R}$ ; (g) a feasible solution for module-placements of operation 1 ~ 5 on an  $8 \times 8$  array.

the D/M phase with different clock frequencies.

Two different methods can implement this biochip design using multiple clock frequencies, with negligible extra cost, based on the hardware setup shown in Figure 2.5. The first method uses the control software to switch the working frequency of the biochip. Since the output frequency of the signal generator can be controlled by the software, the frequency can be adjusted dynamically during the execution of the bioassay. Recent work in a different context, viz. to understand the reliability impact of multiple frequencies, has demonstrated the feasibility of such a hardware setup [116].

The second method uses a tunable frequency-divider implemented on the field-programmable gate array (FPGA) of the cyberphysical system, as shown in Fig-

ure 5.2. Based on the feedback from the sensors, the tunable frequency divider can adjust the frequency of the output signals that are applied on the biochip.

In the D/M phase, the biochip operates at a nominal frequency (for example,  $f_{D/M} = 8$  Hz), while in the T phase, higher-frequency signals (for example,  $f_T = 16$  Hz) are applied to the electrodes. The time spent on dispensing and transporting droplets can be reduced significantly without additional degradation of electrodes or any additional cost in hardware.

Since the time spent on each dilution/mixing operation is determined by sensor feedback rather than a pre-determined module library, we can derive a “semi-deterministic” design for biochips with the consideration of timing uncertainties. The design includes the synthesis result (Section 5.3), and droplet transportation paths in each T phase (Section 5.4).

### 5.3 Operation-dependency-aware synthesis

In this section, we describe how synthesis results can be achieved in the presence of completion-time uncertainties of fluidic operations. Using the proposed algorithm, we can obtain the synthesis results that include: (i) the module-placement for each operation; (ii) the set of operations to be implemented in each D/M phase. It is important to note that, the exact start time and end time of operations are not included in the results derived by the proposed synthesis algorithm; they are determined based on the feedback from sensors during the bioassay run-time. Therefore, the derived synthesis results are semi-deterministic.

The proposed synthesis algorithm focuses on the interdependency among dilution/mixing operations that are given by the sequencing graph of a bioassay. A sequencing graph is an abstract description for a bioassay; each node in it represents a fluidic operation, and each edge represents the interdependency for a pair of operations. For any two operations  $O_a$  and  $O_b$ , if the output droplet of  $O_a$  is the input

of  $O_b$ , then there is an edge from  $O_a$  to  $O_b$ . The sequencing graph in this method is reduced by deleting all nodes that represent dispensing operations. Two examples of sequences graphs for bioassays are shown in Figure 5.3(a) and Figure 5.3(b), respectively.

A sequencing graph for a bioassay has two important properties: (i) it is a directed acyclic graph, because there is no infinite loop or a repeated step under identical conditions in an assay protocol; (ii) the numbers of input droplets and output droplets for each operation are no more than 2. Therefore, the in-degree and out-degree of each node in the sequencing graph are at most 2.

In the following parts, we first introduce the synthesis algorithm for sequencing graphs with the structure of directed-trees, and then introduce the steps for synthesizing a bioassay in the general case.

### 5.3.1 *Synthesis for sequencing graphs with directed tree structure*

First we study bioassays whose sequencing graphs are directed trees. Examples are shown in Figure 5.3(a) and Figure 5.3(b). The node without children nodes in Figure 5.3(a) and the node without parent nodes in Figure 5.3(b) are defined as the root nodes of the directed trees. The node without parent nodes in Figure 5.3(a) and the node without children nodes in Figure 5.3(b) are defined as the leaf nodes of the directed trees. The operations represented by these leaf nodes are defined as “the lowest-level operations” of the bioassay.

The difference between these two sequencing graphs is that, all edges in Figure 5.3(a) are directed towards the root of the tree, while in Figure 5.3(b), all edges are directed away from the root. After switching the directions of all of the edges, the directed tree in Figure 5.3(b) can be analyzed in the same way as the one in Figure 5.3(a). Thus, we use the structure with all edges directed towards the root of the tree (shown in Figure 5.3(a)) to analyze the proposed synthesis procedure.

In the synthesis procedure, starting from the lowest-level operations, we can determine the schedule and module-placement for the operations on a level-by-level basis. Consider the following example. Operations 1, 2, and 6 are three mixing operations shown in Figure 5.3(a). Here 1 and 2 are the lowest-level operations and their outputs are the inputs of 6, hence 1 and 2 must be completed before 6 starts. Based on the interdependency relationship, operations 1 and 2 are implemented in the same D/M phase, while the operation 6 is schedule to be implemented in the next D/M phase, as shown in Figure 5.3(c). If we write the set of operations to be implemented at the  $i$ -th D/M phase as  $S_i$ , then the schedules of operations 1, 2, and 6 can be written as:  $\{1, 2\} \subseteq S_1$  and  $\{6\} \subseteq S_2$ .

Next, mixing operations 1 and 2 are mapped to two mixers on the biochip. The sizes of widely-used mixers on digital microfluidic biochip can be found in [21][32]. As in prior work [32; 51; 64; 96; 115], segregation cells are set as wrappers for each mixer in order to isolate droplets that are being manipulated concurrently on the biochip. Since the mixing operation 6's inputs are the outputs of operations 1 and 2, we can refer to the region that overlaps with the modules for 1 and 2 as the "execution region" of operation 6, as shown in Figure 5.3(d). After the mixing operation has been completed for each mixer, the product droplet stays inside the mixer until the end of the D/M phase, i.e., part of the mixer works as a "storage" unit. Therefore, in the synthesis approach, there is no need to assign specific storage modules. An example is as follows.  $S_1$  and  $S_2$  in Figure 5.3(e) represent the storage units inside the mixers assigned to operations 1 and 2, respectively. Since the execution region of operation 6 overlaps with  $S_1$  and  $S_2$ , the outputs of mixing operations 1 and 2 can be "fed" directly into operation 6 without any module-to-module transportation. After operation 6 is completed, the storage unit for the product droplet of operation 6 will overlap with either  $S_1$  or  $S_2$ .

In this way, the module-placement and schedule for operations 1, 2, and 6 are

obtained. After operation 6 is finished, the execution region of operation 6 will be assigned for operation 8.

Next, operations 1, 2, 6, and 8 are packaged as a “macro-operation”  $M_{S_L}$ ; similarly, operations 3, 4, 7, and 9 are packaged as a “macro-operation”  $M_{S_R}$  as shown in Figure 5.3(f). The schedule for operations 1 ~ 4 and 6 ~ 9 are:  $\{1, 2, 3, 4\} \subseteq S_1$ ,  $\{6, 7\} \subseteq S_2$ , and  $\{8, 9\} \subseteq S_3$ .

Similarly, the placement of modules for  $M_{S_L}$ ,  $M_{S_R}$  and  $N_R$  in Figure 5.3(f) can be determined based on their interdependency. The module for  $M_{S_L}$  will be placed “beside” the region occupied by  $M_{S_R}$ , and after the completion of  $M_{S_L}$  and  $M_{S_R}$ ,  $N_R$  will be mapped to the same region that is assigned to  $M_{S_L}$  and  $M_{S_R}$ . In this way the schedule and resource assignment results for all the operations shown in Figure 5.3(a) can be derived level by level.

Suppose we arbitrarily pick a node  $N_R$  from the directed-tree structure shown in Figure 5.3(a), and write the set of operations on the left and right sub-trees of  $N_R$  as  $S_L$  and  $S_R$ , respectively. Then the derived synthesis results of the proposed operation-interdependency-aware synthesis algorithm have the following three characteristics:

**Characteristic 1:** Operations in  $S_L$  and  $S_R$  do not share any on-chip resources, i.e., they are executed in two separate regions of the biochip.

**Characteristic 2:** Assume that  $E_{S_L}$  and  $E_{S_R}$  are the sets of electrodes where operations in  $S_L$  and  $S_R$  are conducted, respectively, and  $E_{N_R}$  is the set of electrodes that is assigned to operation  $N_R$ , then we have:  $E_{N_R} \subseteq (E_{S_L} \cup E_{S_R})$ .

**Characteristic 3:** If the storage units assigned for operations in  $S_L$  and  $S_R$  are written as  $S'_{S_L}$  and  $S'_{S_R}$ , respectively, and the storage unit assigned to operation  $N_R$  is written as  $S_{N_R}$ , then we have:  $S_{N_R} \subseteq (S'_{S_L} \cup S'_{S_R})$ .

Based on Characteristic 2, we conclude that the resource bound to an operation (i.e., the module-placement) is determined in turn by its predecessor operations. For

FIGURE 5.4: (a) Partitioning of a sequencing graph; (b) the interdependency of macro-operation  $M_T$ , operation  $L$  and operation  $R$ .

a sequencing graph with a directed-tree structure, the resources for other operations can be determined easily when resources assigned to operations represented by leaf nodes are determined.

For instance, the synthesis result for the sequencing graph shown in Figure 5.3(a) can be determined as follows. According to the proposed resource binding steps, the modules for operations 1 and 2 will be placed beside each other, and the modules for operations 3 and 4 also will be placed beside each other. Since operations that are scheduled in the same D/M phase are performed concurrently, we assume that the size of the mixers allocated to all these operations are also the same. Without loss of generality, we can assume that operations 1 ~ 5 are executed in  $1 \times 4$  mixers. The corresponding result for the placement of the modules on a  $7 \times 7$  array is shown in Figure 5.3(g). Each mixing module has one storage unit inside. When the mixing operation is completed, the product droplet stays inside the corresponding storage unit. Based on the module-placement for operations 1 ~ 5, module-placement for other succeeding operations can be derived. For example, the regions where operations 1 and 2 are implemented will be assigned to their successor operations. In this way, the module placement of operations in the directed-tree structure are determined. The schedules of operations in the directed-tree can also be determined based on their input/output interdependency.

### 5.3.2 Synthesis for sequencing graphs in general cases

For sequencing graphs that are not directed trees (i.e., there are nodes whose out-degrees are greater than 1, as shown in Figure 5.4(a)), we can derive their synthesis results using the following steps:

1. **Graph partitioning:** determine the set of nodes  $\{N_{n_1}, N_{n_2}, \dots, N_{n_k}\}$  whose out-degrees are greater than 1, then remove all the edges directed away from these nodes. Then the graph is partitioned into multiple directed trees  $\{T_1, T_2, \dots, T_n\}$ , and each node in  $\{N_{n_1}, N_{n_2}, \dots, N_{n_k}\}$  becomes the root node in a directed tree.
2. **Synthesis for directed trees:** apply operation-interdependency-aware synthesis to each directed tree, and derive the corresponding synthesis result.
3. **Sorting of directed trees:** for any pair of trees  $T_A$  and  $T_B$ , suppose there exists a node  $O_{T_{A_1}} \in T_A$  and a node  $O_{T_{B_1}} \in T_B$ , such that  $O_{T_{A_1}}$  is the predecessor of  $O_{T_{B_1}}$ . Then we express the relationship between trees  $T_A$  and  $T_B$  as  $T_A < T_B$ . Any two elements  $T_x$  and  $T_y$  in  $\{T_1, T_2, \dots, T_n\}$  may stand in any of three mutually exclusive relationships to each other:  $T_x < T_y$ , or  $T_x > T_y$ , or  $T_x = T_y$  (neither of the other two). The conflicting case (i.e., “ $T_x < T_y$  and  $T_x > T_y$ ”) will never occur. The proof can be found in Lemma 5.3.1 of this section.
4. **Merge the synthesis results:** the synthesis result of  $\{T_1, T_2, \dots, T_n\}$  are merged together based on their order. If  $T_x < T_y$  then operations in  $T_x$  must be implemented before  $T_y$ ; if  $T_x > T_y$  then operations in  $T_x$  must be implemented after  $T_y$ ; if  $T_x = T_y$  then operations in  $T_x$  and  $T_y$  are implemented in parallel.

Based on the method of graph partitioning, we have the following lemma:

FIGURE 5.5: Assume two directed trees  $T_x$  and  $T_y$  have the relationships that  $T_x < T_y$  and  $T_x > T_y$ .

**Lemma 5.3.1.** *For any two elements  $T_x$  and  $T_y$  in the set of directed tree  $\{T_1, T_2, \dots, T_n\}$  partitioned from a sequencing graph, the conflict relationship “ $T_x < T_y$  and  $T_x > T_y$ ” never occurs.*

*Proof:* This lemma can be proved by *reductio ad absurdum*. First we assume that these two directed tree have the relationships  $T_x < T_y$  and  $T_x > T_y$ . Then as shown in Figure 5.5, we can find two nodes  $O_{x1} \in T_x$  and  $O_{y1} \in T_y$ , such that  $O_{x1}$  is the predecessor of  $O_{y1}$ ; we can also find two node  $O_{x2} \in T_x$  and  $O_{y2} \in T_y$ , such that  $O_{y2}$  is the predecessor of  $O_{x2}$ . Without loss of generality, here we draw the node  $O_{x1}$  as the immediate predecessor of  $O_{y1}$ , and the node  $O_{y2}$  as the immediate predecessor of  $O_{x2}$ .

Next we can prove that  $O_{x1}$  is the root node for  $T_x$ . As introduced in Section 5.4, we first find out all the nodes  $\{N_{n1}, N_{n2}, \dots, N_{nk}\}$  whose out-degrees are more than 1. Then remove all the edges directed away from these nodes. Hence in the trees we derived from the partitioning procedure, the out-degrees of all the nodes except the root node is equal to 1. The out-degree of the root node is equal to 0. Assume  $O_{x1}$  is not the root of  $T_x$ . Then in  $T_x$ , there must be an edge from  $O_{x1}$  to another node in  $T_x$ . As shown in Figure 5.5, there is another edge from node  $O_{x1}$  to  $O_{y1}$ . Therefore, the out-degree of  $O_{x1}$  in the original sequencing graph (i.e., the sequencing graph before being partitioned) is equal to 2.

Based on the step of graph partitioning,  $O_{x_1}$  whose out-degree is equal to 2, must be a root node of a directed tree derived. Hence we have reached the conclusion that  $O_{x_1}$  is the root node for  $T_x$ . Similarly, we can reach the conclusion that  $O_{y_2}$  is the root node for  $T_y$ .

Then based on the characteristic of directed tree, there must exist a directed path from the node  $O_{x_2}$  toward the root node  $O_{x_1}$  in  $T_x$ , and there must exist a directed path from the node  $O_{y_1}$  towards the root node  $O_{y_2}$  in  $T_y$ . Since there are the edges from  $O_{x_1}$  to  $O_{y_1}$ , and the edge from  $O_{y_2}$  to  $O_{x_2}$ , we get a directed circle that connects the nodes  $O_{x_1}$ ,  $O_{x_2}$ ,  $O_{y_1}$  and  $O_{y_2}$  in the sequencing graph. However, as introduced in Section 5.3, a sequencing graph for bioassay will not have a directed cycle.

Hence we have proved that, the conflict relationships between  $T_x$  and  $T_y$  will not exist. This completes the proof of the lemma.  $\square$

From the above steps, the synthesis results can be derived for general sequencing graphs. An example is shown in Figure 5.4(a). The graph is divided into three parts: the node that represents operation  $L$ , the node that represents operation  $R$ , and a directed tree  $T$ . The operations in  $T$  are packaged as a “macro-operation”  $M_T$ . As operation  $L$  and  $R$  both are predecessors of operations in  $T$ , the interdependency of macro-operation  $M_T$ , operation  $L$  and operation  $R$  is show in Figure 5.4(b). According to the above discussion, the relationship among  $R$ ,  $L$ , and  $M_T$  can be written as  $R = L > M_T$ .

Therefore, operations  $L$  and  $R$  will be executed concurrently, and operations in  $M_T$  will be executed after operations  $L$  and  $R$  are both completed. The corresponding module-placement result can be derived in a similar way as the sequencing graph shown in Figure 5.3(f).

The operation-interdependency-aware algorithm described above can derive the semi-deterministic synthesis result for a bioassay. The synthesis result assigns each dilution/mixing operation to a specific D/M phase, while completion-times of these

FIGURE 5.6: Pseudocode for operation-interdependency-aware synthesis.

operations are determined on-line during the execution of the bioassay. The robust module-placement thus derived is independent of the execution time of each operation. When timing uncertainties of dilution/mixing operations exist, the module-placement of a bioassay remains unchanged. The pseudocode for the entire operation-interdependency-aware synthesis approach is shown in Figure 5.6.

## 5.4 Droplet-routing procedure

The practical application of cyberphysical microfluidics requires control software to ensure the synthesis results of the bioassay are routable, and also, to determine droplet transportation paths for each droplet transportation phase.

As introduced in Section 5.2, in the D/M phase, the biochip will stop an operation when the feedback from sensors indicates the operation has been finished. Then the output droplet will be stalled inside the modules, and will wait to be used as the input of the following operation in the next D/M phase. In each T phase, all the dilution/mixing operations implemented in the last D/M phase have already finished, and their output droplets of operations are stalled in their modules. The electrodes where these droplets stay, as well as their neighboring electrodes, are considered as “obstacles” for droplet transportation. The droplet transportation paths cannot overlap with the obstacles, otherwise interference between droplets may occur.

The transportation of droplets during a bioassay consists of three parts: moving droplets from one module to another module; moving droplets from on-chip reservoirs to the modules; and moving the “extra product droplets” to waste reservoirs. For some bioassays, it is important to note that not all of the intermediate product droplets are used for subsequent operations. Those product droplets that are not used in the bioassay are defined as extra product droplets, and they must be collected in the waste reservoir.

As introduced in Section 5.3, the placements of modules for dilution/mixing operations are determined based on their input/output interdependencies. For any droplet that contains an intermediate product of the bioassay, the module where the droplet is generated and the module where it will participate during the next operation, are overlapped. The output droplets of each module only need to “wait” at the original position; they will be directly “fed” into the module of the following operation. Therefore, the transportation of droplets from modules to modules can be eliminated. Only droplet transportation from reservoirs to modules and from modules to the waste reservoir need to be considered in the T phase.

In this section, first we consider the routability for the result derived by the operation-interdependency-aware synthesis approach. Then the method of online decision-making on the transportation paths of droplets is introduced.

#### 5.4.1 Routability analysis

If we randomly select an operation  $O_N$  from the sequencing graph, and the immediate predecessor operations of  $O_N$  are written as  $O_L$  and  $O_R$ , then we have the following lemma:

**Lemma 5.4.1.** *Transportation paths from a reservoir  $R$  to the module of  $O_N$  exist if there are transportation paths from the reservoir to the modules of immediate predecessor operations  $O_L$  and  $O_R$ .*

*Proof:* The existence of transportation paths from the reservoir  $R$  to the modules of operations  $O_L$  and  $O_R$  means that paths from the reservoir to the modules can be found when there are obstacles  $R_{AB}$  on the biochip. Here, the set of storage units and their neighboring electrodes is written as  $R_{AB}$ . Even if no droplet stays on the storage unit, we still consider the “empty” storage unit (and its neighboring electrodes) as obstacles.

The set of obstacles is written as  $R_N$  when we search for the transportation path from the reservoir to the module of operation  $R_N$ . Based on Characteristic 3 of the results derived by the operation-interdependency-aware synthesis procedure proposed in Section 5.3, the droplet that stays in module  $O_N$  is restricted to be inside one of the regions that have ever been assigned as storage units for operation  $O_L$  and  $O_R$ .

Thus we have  $R_N \subseteq R_{AB}$ , i.e., each electrode in the obstacle  $R_N$  is contained by obstacle  $R_{AB}$ .

We have already assumed that the routing problem has a solution with the existence of obstacle  $R_{AB}$ . Therefore, with the existence of  $R_N$ , there must exist a routing solution from the reservoir to the module of  $O_N$ . This completes the proof of the lemma.  $\square$

During the execution of bioassays, the input droplets for  $O_N$  can come from different reservoirs, while it is important to note that Lemma 5.4.1 is insufficient to ensure the existence of the transportation from any on-chip reservoir to the module for  $O_N$ . Therefore, in order to guarantee that droplets dispensed from any on-chip reservoir can be transported to the module of  $O_N$ , the droplet-routing paths between reservoirs need to be considered.

In the synthesis result of a bioassay, for each operation, if there exist transportation paths to move its input droplets into the module and there exist transportation paths to move the extra droplets into the waste reservoir, then the synthesis result is

“routable”. By applying Lemma 5.4.1 to the sequencing graph with the directed-tree structure, as well as considering the differences between reservoirs, we can further derive the following lemma that gives the sufficient conditions for routability of synthesis results:

**Lemma 5.4.2.** *For a given bioassay whose sequencing graph is a directed-tree, its corresponding synthesis result is routable if the following two constraints are satisfied:*

*Constraint 1: There exist transportation paths that connect all the modules of the lowest-level operations and their corresponding reservoirs. Here the “lowest-level operations” is defined as “the operations that are represented by leaf nodes in the sequencing graph of bioassay”.*

*Constraint 2: There exist transportation paths that connect all the on-chip reservoirs.*

*Proof:* We write the set of modules corresponding to the lowest-level operations in the sequencing graph,  $M_{\text{leaf}}$ , as  $\{M_{L_1}, M_{L_2}, \dots, M_{L_N}\}$ , and the set of reservoirs  $R^*$  as  $\{R_1, R_2, \dots, R_r\}$ .

For each reservoir  $R_i$ , the sequencing graph of the bioassay defines the set of modules whose input droplets come from  $R_i$ . For example, if the input sample/reagent of  $\{M_{L_{i_1}}, M_{L_{i_2}}, \dots, M_{L_{i_k}}\}$  is stored in reservoir  $R_i$ , then the droplets dispensed from  $R_i$  need to be transported to these modules.

Constraint 1 ensures that there exist transportation paths from reservoir  $R_i$  to modules  $\{M_{L_{i_1}}, M_{L_{i_2}}, \dots, M_{L_{i_k}}\}$ . Constraint 2 ensures that the reservoirs  $\{R_1, R_2, \dots, R_r\}$  are interconnected by transportation paths. Hence for any arbitrarily chosen reservoir in  $R^*$ , and any arbitrarily chosen module from  $M_{\text{leaf}}$ , there exist transportation paths between them.

Then based on Lemma 5.4.1, we know that there exist transportation paths from any reservoir in  $R^*$  to any immediate successor operation of these lowest-level

operations.

By applying Lemma 5.4.1 level-by-level to the sequencing graph until we reach the root node, we find that there exist transportation paths from a reservoir in  $R^*$  to the module corresponding to any operation in the bioassay. Hence for each operation, there exist transportation paths from the corresponding reservoirs to the module of the operation, no matter which reservoir the input droplet comes from. Therefore, the synthesis result is routable. This completes the proof of the lemma.  $\square$

#### 5.4.2 *Searching droplet-routing paths*

As discussed in Section 5.3, the synthesis results derived by the operation-interdependency-aware synthesis procedure is independent of the execution time of operations. For each T phase, the corresponding module-placement configuration remains unchanged when the execution time of the operations varies. The routability of the synthesis result, the starting position and destination of each droplet, as well as the positions for storage units of droplets, have already been determined before the execution of a bioassay. With this available information, the droplet transportation paths for each T phase can be derived by the algorithms proposed in previous publications [28; 117; 118; 119].

#### 5.4.3 *Online decision-making for droplet-routing*

By applying the operation-interdependency procedure discussed in Section 5.3 and the computation steps for droplet transportation as discussed above, we can derive the following information before the execution of bioassay: (i) schedule of operations, i.e., the set of operations to be implemented in each D/M phase; (ii) module-placement for operation that are not affected by timing uncertainties in the execution of fluidic operations; (iii) droplet transportation paths for each T phase.

Since the uncertainties about execution times for the fluid-handling operations

have no influence on the routability of the synthesis results or the transportation paths of droplets, routing paths can be derived before the execution of the bioassay by applying  $A^*$  algorithm [28]. The response time of on-line decide-making for the cyberphysical system is not affected by the computational complexity of the  $A^*$  droplet routing algorithm.

During bioassay run-time, the control software only needs to make on-line decisions about when a dilution/mixing operation can be deemed to have been completed based on sensor feedback. Assume that the maximum number of dilution/mixing operations that are concurrently being executed on the biochip is  $\mathcal{N}$ , and the computational complexity of processing the feedback signal for one operation is  $O(1)$ , then the computational complexity for on-line decision-making during the execution of bioassay is  $O(\mathcal{N})$ . As the computational complexity is low, the response time of the control system is negligible.

Based on the pre-determined module-placement results and droplet transportation paths, the bioassay can be performed under the completion-time uncertainties and yet provide high accuracy in the final reaction outcome.

## 5.5 Simulation results

In this section, we first present the simulation results for three widely used laboratory protocols, namely exponential dilution of a protein sample, interpolation dilution of a protein sample, and polymerase chain reaction (PCR), respectively [32]. The sequencing graph and the detailed description of the protocol for these bioassays can be found in [32]. We compare our results with prior work on biochip synthesis in [32], and a recently published cyberphysical software-based recovery method based on a greedy algorithm [51][96]. The same as all prior work in this area, both these baseline methods are oblivious of timing uncertainties in fluidic operations.

In order to compare the uncertainty-oblivious baseline methods with the proposed

design method, and study the synthesis results in the presence of timing uncertainty, in this section the baseline methods are adjusted using three methods: (i) adding additional time to module library specifications; (ii) running dynamic re-synthesis when a timing overshoot is detected; and (iii) adding interruption whenever there is a timing overshoot.

#### 5.5.1 Yield estimation for biochips with no feedback-based adaptation

As discussed in Section 5.1, the execution time of a fluidic operations needs to be considered as a random variable rather than a known constant. If no feedback-based control is used and the synthesis of the biochip only relies on a module library with constant operation times, there is a high likelihood that many operations cannot complete within the allocated time. The outputs of these “unfinished operations” will be unqualified droplets, and the outcome of the bioassay will be unacceptable.

Next we compute the probability that a bioassay will fail due to the occurrence of unfinished operations. Assume that the execution time for each operation is Gaussian random variable, and for any two operations in a bioassay, their execution times are independent of each other. Suppose that for any operation  $O_i$ , its completion time  $T_i$  has mean value  $\mu_i$  and variance  $\sigma_i^2$ .

If we define the time spent on operation  $O_i$  as  $T_i = \mu_i + \sigma_i$ , and the real execution time  $T_i^*$  does not exceed  $T_i$ , then  $O_i$  will be executed correctly; otherwise  $O_i$  is deemed to have failed. A bioassay terminates with an acceptable outcome only if all the operations are executed correctly. Let  $P_i$  be the probability that a dilution/mixing operation  $O_i$  is executed correctly, and let the number of dilution/mixing operation in a bioassay be  $N_b$ . Then the probability  $P_{\text{success}}$  that the bioassay is successfully implemented is given by:  $P_{\text{success}} = \prod_{i=1}^{N_b} P_i = P^{N_b}$  (if  $P_i = P$  for any  $i$ ).

Therefore, the probability of successful implementation  $P_{\text{success}}$  decreases expo-

Table 5.1: Probabilities of bioassays being successfully implemented without unfinished operations.

Bioassay	No. of dilution/ mixing operations	$P_{\text{success}}, T_i$ listed		
		$\mu_i$	$\mu_i + \sigma_i$	$\mu_i + 2\sigma_i$
PCR	7	0.01	0.30	0.85
Interpolating dilution	35	$\sim 0$	$\sim 0$	0.45
Exponential dilution	47	$\sim 0$	$\sim 0$	0.34

nentially with the number of dilution/mixing operation. Hence for a realistic bioassay with a large number of fluidic operations, the compound yield will be unacceptably low.

Next, based on above discussion, we compute the numerical values of  $P_{\text{success}}$  for three test-case bioassays. Let  $T_i$  be the time spent on operation  $O_i$  when a static synthesis method is used based only on a module library, and  $P_i$  be the probability that  $O_i$  is successfully completed before the next operation is started. Based on the characteristics of the Gaussian distribution, if we set the time spent on operation  $O_i$  as  $T_i = \mu_i + \sigma_i$ , then  $P_i = 0.84$ ; if we set  $T_i = \mu_i + 2\sigma_i$ , then  $P = 0.98$ . Table 5.1 lists the probabilities that bioassays are successfully completed (i.e., with no unfinished operations) when no cyberphysical adaptation is used. When we conservatively set  $T_i = \mu_i + 2\sigma_i$  (and increase the operation times considerably) and obtain  $P_i = 0.98$ , the probability for successfully implementing the exponential mixing of protein bioassay is still low, only 0.34. We can further calculate that, in order to improve the yield of the exponential dilution bioassay to 0.90 and above, we need to set  $T_i = \mu_i + 4\sigma_i$ .

We therefore conclude that the bioassay execution on conventional biochip platforms without a sensing system, closed-loop control, or uncertainly-aware synthesis, will lead to unacceptably low bioassay yield and low confidence in reaction outcomes.

From Table 5.1, we also find that  $P_{\text{success}}$  can be increased by increasing  $T_i$ .

However, on the other hand, increasing  $T_i$  will elongate the reaction completion time, and increase the risks of excessive heating and evaporation of droplets [120]. Therefore  $T_i$  should be set to be within a reasonable range. Due to the lack of sufficient data thus far from real experiments on fabricated chips, the additional probability of bioassay failure caused by excessive heating and evaporation is not considered here. In this way, we do not quantify this important shortcoming of the baseline methods that we use for comparison.

Next we compare the bioassay completion times of the parallel recombinative simulated annealing (PRSA)-based synthesis algorithm [32][121] with the proposed operation-interdependency-aware synthesis algorithm. Here we use the module library defined in [32], and run simulations by considering timing uncertainty. We assume that for each operation, its average execution time  $\mu_i$  is the time defined in the library, and  $\sigma_i$  is  $0.1\mu_i$ . For example, for a dilution operation executed on a  $2 \times 3$  array,  $\mu_i = 6$  seconds, and  $\sigma_i = 0.6$  second.

In order to increase the yield for the baseline design, when we run the PRSA-based algorithm, we add extra execution time  $\Delta T_i$  for each operation. In the simulations, we assume that the PCR bioassay, the exponential dilution bioassay, and the interpolation dilution bioassay are all executed on an  $8 \times 8$  direct-addressing array.

The simulation results with  $\Delta T_i$  set to  $\sigma_i$ ,  $2\sigma_i$ , and  $4\sigma_i$  are shown in Table 5.2. The completion time of the bioassays derived by PRSA-based algorithm increases with  $\Delta T_i$ , and it is discovered that by applying the proposed method, time-to-results of bioassays can be reduced.

As shown in Table 5.2, for exponential dilution and interpolation dilution bioassays, the completion time derived by PRSA algorithm increases only slightly when the execution time for each dilution/mixing operation increases. It can be explained that for these two bioassays, most of the execution time is spent on droplet transportation operations, whose execution times are known to have low variability.

Table 5.2: Comparison of bioassay completion time derived by PRSA-based algorithm [32] and proposed method.

Bioassay	Completion time (s)				
	PRSA-based algorithm [32], $\Delta T_i$ listed				Proposed method
	0	$\sigma_i$	$2\sigma_i$	$4\sigma_i$	
PCR	26	28	31	35	25
Interpolation dilution	177	184	195	201	158
Exponential dilution	195	196	202	208	182

FIGURE 5.7: Comparison between the number of droplets consumed in the biochips of [51][96] (droplet consumptions are the same for the methods of these two papers) and the proposed method.

### 5.5.2 Number of droplets consumed

For the synthesis algorithm proposed in [51][96], bioassays need to be characterized before they are executed on the biochip. In the characterization procedure, each operation needs to be executed at least three times [113]. The comparison of the number of droplets consumed for each bioassay in [51][64][96] and the proposed design is shown in Figure 5.7. Note that the prior methods consume the same number of droplets each. We find that the number of droplets is greatly reduced in the proposed design based on a cyberphysical platform and uncertainly-aware synthesis.

Table 5.3: Synthesis results derived by the operation-interdependency-aware synthesis approach on direct-addressing biochips.

Bioassay	Size of the biochip	Completion time (s)		
		D/M phases	T phases	Total
Exponential dilution bioassay	$8 \times 8$	57	125	182
	$9 \times 9$	32	106	138
	$10 \times 8$	37	117	154
	$12 \times 8$	22	145	167
Interpolation dilution bioassay	$8 \times 8$	44	114	158
	$9 \times 9$	29	102	131
	$10 \times 8$	32	114	146
	$12 \times 8$	21	130	151

### 5.5.3 Results derived by the operation-interdependency-aware synthesis approach on pin-limited biochip

We assume that the completion times of mixing operations performed by different kinds of mixers are the same as the data defined in the module library in [32]. If the bioassays are mapped to direct-addressing biochips, the synthesis results derived by the operation-interdependency-aware synthesis approach can be found in Table 5.3. Here the completion time of D/M phases is defined as the sum of time spans for all the D/M phases in the bioassay. The completion time of T phases is defined as the sum of time spans for all the T phases in the bioassay. The working frequency of T phase is set as 1 Hz.

### 5.5.4 Response time in the presence of timing uncertainties

In the re-synthesis algorithm proposed in [51], when a sensor detects that the status of a droplet is different from expected result, e.g., an operation has not finished within the pre-determined time, a re-synthesis procedure will be performed. The control software dynamically updates the synthesis steps using a greedy algorithm, and the operation with unexpected completion time will be re-executed in the re-synthesis result. To compare with [51], we first randomly select a fluidic operation, and assume

Table 5.4: Comparison of response times (one fluidic operation with timing uncertainty).

Bioassay	Operations with uncertainty	Response time (s)	
		Greedy algorithm [51]	Proposed algorithm
Exponential dilution bioassay	$Dlt_{39}$	0.34	$\sim 0$
	$Dlt_{12}$	4.97	$\sim 0$
	$Dlt_4$	2.44	$\sim 0$
	$Dlt_{12}$	1.47	$\sim 0$
	Average (s)	1.12	$\sim 0$
Interpolation dilution bioassay	$Dlt_{15}^*$	0.91	$\sim 0$
	$Dlt_8^*$	1.23	$\sim 0$
	$Dlt_{19}^*$	1.45	$\sim 0$
	$Dlt_{16}^*$	0.34	$\sim 0$
	Average (s)	0.85	$\sim 0$

its execution time is longer than the time defined in the module library. Then after the re-synthesis procedure is triggered, the response time for the re-synthesis procedure in [51] is recorded. Here the response time is defined as the CPU time spent in deriving resynthesis solutions when the timing overshoot is detected. During on-line re-synthesis, all fluid-handling operations for the bioassay are suspended.

The simulation is repeated 20 times (with different operation with uncertainty injected each time), and a snapshot of the results is shown Table 5.4. The simulation is carried out on a 2.30 GHz Intel i3 processor with 8 GB of memory. Compared to the greedy algorithm [51], the response time is significantly reduced using the proposed design. Note that in the simulations, we insert only one fluidic operation with timing uncertainties; however in a real application, each operation may have timing uncertainty. Therefore, in the design of [51][96], the re-synthesis procedure will be carried out multiple times, and the CPU time for extensive on-line re-synthesis of the entire bioassay will be considerable. Even a few seconds of CPU time for re-synthesis will be magnified for multiple operations and pose a serious problem for applications such as flash chemistry [96][122].

### 5.5.5 Number of operations interrupted under uncertainty

Suppose we run the synthesis results derived by the PRSA-based algorithm on a cyberphysical biochip. If the execution time of an operation  $O_{\text{longer}}$  is longer than the time defined by the module library, then the controller can stop all other operations until operation  $O_{\text{longer}}$  is completed. In this way, time-consuming on-line re-synthesis can be avoided. However, the executions of other operations have to be interrupted.

Based on the Gaussian assumption in Section 5.5.1, the probability that an operation's execution time is longer than the time defined in the module library is 0.5, if we do not add extra execution time for each operation. We simulate the bioassay and count the number of operations that must be interrupted. During the execution of bioassay, an operation may be interrupted multiple times; however, we count such cases as one interrupted operation. Hence the number of interruptions reported for the baseline method is less than the actual number of interruptions experienced.

The total number of operations, and the number of operations that are interrupted in the three bioassays, are listed in Table 5.5. We note that nearly all the operations are interrupted for the synthesis results derived using the PRSA-based algorithm. The interruptions that occur during the execution of the bioassay may influence the quality of output droplets [51]. On the other hand, in the proposed algorithm, no operations are interrupted, and the assay proceeds in an unimpeded manner.

### 5.5.6 Completion time with multiple clock frequencies on pin-limited biochip

For the biochip with multiple clock frequencies, if we increase the clock frequency for T phase, then the execution time for the bioassay can be reduced. When bioassays are executed on a  $8 \times 8$  direct-addressing biochip, the relationship between execution time of bioassays and the clock frequency of the T phase is shown in Figure 5.8.

By increasing  $f_T$  from 1 Hz to 10 Hz, the execution time for exponential dilution

Table 5.5: Comparisons for the number of operation interrupted between PRSA-based algorithm [32] and the proposed method.

Bioassay	Total no. of operations	No. of operations interrupted [32]	No. of operations interrupted (proposed method)
Exponential dilution	103	97	0
Interpolating dilution	71	65	0
PCR	15	3	0

FIGURE 5.8: The relationship between completion time of bioassays and  $f_T$  on an  $8 \times 8$  direct-addressing biochip.

bioassay can be reduced from 182 seconds to 70 seconds. The completion time for interpolation dilution and PCR are also listed in Figure 5.8.

From the simulation results, we find that when the clock frequency of the T phase increases, the completion time of PCR bioassay on the direct-addressing biochip does not decrease significantly. This is because the time for droplet transportation in the PCR bioassay is relatively low.

## 5.6 Chapter summary and conclusions

In this chapter, we have shown how cyberphysical integration in digital microfluidics can be used to carry out on-chip bioassays despite the timing uncertainties inherent in fluidic operations such as mixing, dilution, and thermal cycling. We have presented an operation-interdependency-aware synthesis method that is responsive to such uncertainties. The proposed design approach facilitates dynamic on-line decision-making for the execution of fluidic operations and droplet-routing in response to detector feedback. We have also incorporated the use of multiple clock frequencies to accelerate the time-to-response without any adverse impact on electrode reliability. We have used three common laboratorial protocols to demonstrate that, compared to uncertainty-oblivious biochip synthesis, the proposed dynamic synthesis approach decreases the likelihood of erroneous reaction outcomes, and it leads to reduced time-to-result, less repetition of reaction steps, and less wastage of precious samples and reagents. This work is therefore a step forward towards fully automated on-chip biochemistry with reliable assay outcomes and low cost.

## Pin-Count Minimization for Application-Independent Chips

In this chapter, we propose design methods for pin-limited general-purpose microfluidic biochips. The number of control pins used to drive electrodes is a major contributor to fabrication cost for disposable biochips in a highly cost-sensitive market. Most prior work on pin-limited biochip design determines the mapping of a small number of control pins to a larger number of electrodes according to the specific schedule of fluid-handling operations and routing paths of droplets. Such designs are therefore specific to the bioassay application, hence sacrificing some of the flexibility associated with digital microfluidics. We propose a design method to generate an application-independent pin-assignment configuration with a minimum number of control pins. Layouts of commercial biochips and laboratory prototypes are used as case studies to evaluate the proposed design method for determining a suitable pin-assignment configuration. Compared with previous pin-assignment algorithms, the proposed method can reduce the number of control pins and facilitate the “general-purpose” use of digital microfluidic biochips for a wider range of applications.

## 6.1 Motivation and related prior work

In recent years, the complexity of digital microfluidic biochips continues to increase as new applications are targeted by this platform. For example, recently announced commercial products contain up to 5000 electrodes [123; 124]. In order to ensure complete reconfigurability and the ability to run any given bioassay on the digital microfluidic platform (i.e., “general-purpose use”), it is desirable that every electrode be controlled by an independent pin. However, a one-to-one mapping between control pins and electrodes (referred to as direct-addressing pin-assignment) is not practical for low-cost disposable chips. A large number of control pins leads to high fabrication cost, large form factors and interconnect routing problems [6].

In order to reduce the number of control pins and to control the digital microfluidic array without significantly affecting concurrent droplet operations, a number of design of optimization techniques have been published in the literature. These techniques can be categorized as being either bioassay-independent [36; 37] or bioassay-specific [34][38][65]. In bioassay-independent techniques such as the use of a bus-phase addressing [36] or cross-referencing [37], the number of control pins required for addressing the electrodes is independent of the target application. For example, cross-referencing requires  $m + n$  pins for an  $m \times n$  array of electrodes, analogous to row/column-based addressing in memories. Bioassay-specific pin-assignment methods lead to fewer control pins since they utilize knowledge about the operation schedule, module placement, and droplet routing pathways of the target bioassay.

Prior methods on bioassay-specific pin assignment suffer from three main drawbacks. First, these techniques are not effective for the design of multi-functional biochips, which can be reconfigured post-fabrication for different applications by loading the appropriate control software. General purpose (application-independent) biochips, where software can be used as a differentiator, offer the promise of higher

production volume and reduced cost. Second, fluid-handling operations on an application-specific biochip are constrained by the pre-determined pin-assignment, hence post-fabrication tuning of the bioassay protocol, schedule, and droplet routing are not possible. Finally, it is difficult to estimate the number of control pins *a priori* since the number of pins is application-dependent. The cross-referencing technique described above is application-independent; however, it requires a special electrode structure which both top and bottom plates are divided into discrete electrode arrays. This results in increased complexity and higher manufacturing cost [37].

To overcome the above drawbacks, we propose a new method to generate pin-assignment configurations. This method does not depend on actuation sequences of electrodes, or does the scheduling and the routing of droplets. Any target application can be mapped to the array without any restriction on droplet manipulation. The degree of freedom for droplet movement is therefore maximized.

The main contributions of this chapter are as follows:

1. An analysis of pin-actuation conflicts, and derivation of necessary and sufficient conditions for control-pin sharing to ensure high flexibility in the concurrent movement of two droplets, and freedom of movement of a single droplet in all feasible directions (Section 6.2).
2. An integer linear programming model for designing a pin-assignment with the smallest number of pins (Section 6.3).
3. A graph-theoretic method to formulate an acceptance test for a pin-assignment configuration and a lower bound on the number of pins (Section 6.4).
4. A heuristic algorithm that generates a pin-assignment configuration for biochips (Section 6.4).

5. Extension of the study from  $1\times$  volume droplets to  $2\times$  and even larger droplets (Section 6.5).
6. A scheduling algorithm that can be applied to biochips with pin-constraints (Section 6.6).
7. Results for commercial biochips and experimental prototypes (Section 6.7).

## 6.2 Analysis of pin-assignment

In this section, we discuss the relationship between droplet movement and voltages applied to the electrodes. Next, the concept of pin-actuation conflict is introduced. Finally, several pin-assignment configurations are analyzed in order to determine the conditions that guarantee conflict-free pin-assignment.

### 6.2.1 *Pin-actuation conflicts*

To manipulate a droplet that currently resides on an electrode  $\mathcal{E}$ , appropriate control voltages must be applied to a group of electrodes. According to the principle of electrowetting-on-dielectric (EWOD)-based microfluidic biochips, movements of a droplet are determined by the group of electrodes that are directly in contact with the droplet. Suppose a droplet of unit volume (referred to as a “ $1\times$ ” droplet) is held on electrode  $\mathcal{E}$ . Then the electrode group that can determine the movement of the  $1\times$  droplet consists of the central electrode  $\mathcal{E}$  and all its non-diagonally adjacent electrodes. Each non-diagonally adjacent electrode is a possible destination for the droplet. Figure 6.1(a) presents an example. Each square in Figure 6.1(a) stands for an electrode on the microfluidic biochip; letters such as “A”, “B” and “C” stand for the names of control pins that are connected to the corresponding electrodes. The control voltages applied to the control pins are either “High”, “Low” or “don’t-care”. Here we introduce two definitions:

**Control electrode group (CEG):** An electrode on which the droplet rests at any given time and all other electrodes that have direct contact with the droplet are defined as the elements of the control electrode group (CEG).

For a  $1 \times$  droplet, its CEG includes the central electrode on which the droplet rests and all the non-diagonally adjacent electrodes, see Figure 6.1(a). Most bioassays executed on biochips only include the transportation of  $1 \times$  droplets, hence in the following sections (Section 6.2.2 through Section 6.4), we only discuss the case of  $1 \times$  droplets on the biochip. The pin-assignment problem associated with biochips that have larger droplets on them is discussed in Section V.

**Control pin group (CPG):** All pins that are connected to the electrodes in the CEG are defined as the elements of the control pin group (CPG).

FIGURE 6.1: (a) A central electrode and its non-diagonally adjacent electrodes comprising an electrode group; (b) an example of pin-actuation conflicts; (c) an example where two diagonally adjacent electrodes in the same CEG share one pin (Pin A); (d) an example where two non-adjacent electrodes in the same CEG share one pin (Pin A).

When multiple fluid-handling operations are implemented on a biochip with a given pin-assignment configuration, pin-actuation conflicts must be considered. An example is shown in Figure 1(b), where droplets  $D_1$  and  $D_2$  are on the array, and they are scheduled to move in the directions of the arrows concurrently. The groups of control pins for  $D_1$  and  $D_2$  are  $\{A, B, H\}$  and  $\{A, C, D, H\}$ , respectively. Note that Pin A and Pin H are common (shared) control pins for droplets  $D_1$  and  $D_2$ . In order

to move  $D_1$  in the designated direction, the voltages applied to A, B, H should be set as Low, Low, and High, respectively. Similarly, in order to move droplet  $D_2$ , the voltages of A, C, D, H should be set as High, Low, Low, and Low, respectively. Thus, the movement of  $D_1$  requires the application of “High” voltage on Pin H, while the movement of  $D_2$  requires the application of “Low” voltage on Pin H. Since it is not possible to apply these different voltages to Pin H at the same time, the movements of  $D_1$  and  $D_2$  cannot be implemented concurrently. This problem is referred to as “conflict in pin-actuation signals”.

### 6.2.2 Control-pin sharing and concurrent movement of droplets

To analyze pin-actuation conflicts, we consider an electrode array with any arbitrary pin-assignment configuration. Assume that Droplet 1 and Droplet 2 are on two arbitrarily chosen electrodes in the array and their control electrode groups are written as  $CEG_1$  and  $CEG_2$ , respectively, and these control electrode groups have no overlap with each other. The central electrodes of  $CEG_1$  and  $CEG_2$  are written as  $E_{1C}$  and  $E_{2C}$ , respectively. Note that any pin-actuation conflict involving more than two droplets can be studied as a two-droplet problem by examining all possible pairs of droplets.

Without loss of generality, we first assume that two electrodes  $E_{11}$  and  $E_{12}$  in  $CEG_1$  share one pin (Pin A). Then we have the following scenarios, exhaustively enumerated by Cases (1.a)~(1.c):

(1.a)  $E_{11}$  and  $E_{12}$  are non-diagonally adjacent electrodes: In this case, the movement of a droplet along some directions cannot be achieved because of the electric shorting of adjacent electrodes [125].

(1.b)  $E_{11}$  and  $E_{12}$  are diagonally adjacent electrodes: An example is shown in Figure 6.1(c). Two non-diagonally adjacent electrodes of the droplet are controlled by Pin A. If “High” signal is applied to Pin A, the two electrodes that are connected

FIGURE 6.2: Six pin-assignment configurations that are analyzed in Cases (2.a)~(2.c) and Cases (3.a)~(3.e): (a) Case (2.a); (b) Case (2.b); (c) Case (2.c); (d) Case (3.a); (e) Case (3.c); and (f) Case (3.d).

to Pin A will pull the droplet from two directions at the same time. The droplet may undergo unwanted and unpredictable movement.

(1.c)  $E_{11}$  and  $E_{12}$  are non-adjacent electrodes: An example is shown in Figure 6.1(d). Two non-adjacent electrodes of the droplet are controlled by Pin A. If Pin A activates the two electrodes at the same time, the droplet may be split.

According to above discussion for Cases (1.a)~(1.c), we conclude that in order to avoid unwanted movement or splitting of droplets and also guarantee the flexibility of droplet movements, electrodes in the same CEG cannot share control pins.

Next we assume that  $CEG_1$  and  $CEG_2$  share one pin (without loss of generality,

we assume that the shared pin is Pin A). Then we have the following scenarios, exhaustively enumerated by Cases (2.a)~(2.c):

(2.a) Pin A is connected to both  $E_{1C}$  and  $E_{2C}$ : An example is shown in Figure 6.2(a). The two droplets can be moved concurrently to any non-diagonally adjacent electrode without pin-actuation conflicts. Thus, there are 16 possible concurrent movements of the pair of droplets, and no unwanted movement or splitting will occur for these 16 concurrent movements.

(2.b) Pin A is neither connected to  $E_{1C}$  nor  $E_{2C}$ : An example is shown in Figure 6.2(b). Suppose Droplet 1 and Droplet 2 are scheduled to move in the directions indicated by the arrows. For the movement of Droplet 1, the control voltages applied to Pins A, B, C, D, and E should be set as High, Low, Low, Low, and Low, respectively. Similarly, for the movement of Droplet 2, the control voltages on Pins A, F, G, H, and I should be set as Low, Low, Low, High, and Low, respectively. Therefore, the status of Pin A corresponding to the movements of Droplet 1 and Droplet 2 are different. To avoid a conflict, Droplet 1 and Droplet 2 must be moved in different clock cycles. Assume that Droplet 1 is moved first; a “High” voltage will be applied to Pin A. To make Droplet 2 stay at its current position, a “High” voltage will also be applied to the electrode under Droplet 2 (i.e., a “High” voltage will be applied to Pin F). Note that when a high voltage is applied to the electrode under the droplet, the droplet will remain at its current position without movement or splitting, even if high voltage is applied to one of its adjacent electrodes; this scenario has been demonstrated experimentally [46]. After Droplet 1 has arrived at its destination electrode, the movement operation for Droplet 2 will be implemented. Thus, the number of all possible concurrent movements for the droplet pair is  $3 \times 3 + 1 = 10$ , and no unwanted movement or splitting will occur for these 10 concurrent movements.

(2.c) Pin A is connected to  $E_{1C}$  or  $E_{2C}$ : Without loss of generality, we assume that Pin A is connected to  $E_{1C}$ . An example is shown in Figure 6.2(c). Droplet 1

can be moved in any non-diagonal directions freely, while Droplet 2 can be moved to the electrodes controlled by Pin G, Pin H, and Pin I. Thus, the number of all possible concurrent movements for the droplet pair is  $4 \times 3 = 12$ , and no unwanted movement or splitting will occur for these 12 concurrent movements.

Based on the above analysis for Cases (2.a)~(2.c), we find that when two CEGs share one control pin, and electrodes in the same CEG do not share any control pin, unwanted movement or splitting of droplet will not occur. The number of all possible concurrent movements for the droplet pair varies from 10 to 16. Even though in Cases (2.b) and (2.c) the flexibilities of droplet movements are not as high as direct-addressing biochips, they are still adequate for the concurrent manipulation of droplets.

Finally, we assume that CEG<sub>1</sub> and CEG<sub>2</sub> share two pins (Pin A and Pin B). Then we have the following scenarios, exhaustively enumerated by Cases (3.a)~(3.e):

(3.a) Both  $E_{1C}$  and  $E_{2C}$  are connected to Pin A (or Pin B): Without loss of generality, we assume that both  $E_{1C}$  and  $E_{2C}$  are connected to Pin A. One example is shown in Figure 6.2(d). When Droplet 1 is moved in the direction indicated by the arrow, the control voltages applied to Pins A, B, C, D, and E should be set as Low, High, Low, Low, and Low, respectively. In this case, the electrode under Droplet 2 is applied “Low” voltage, while one of the non-diagonal electrodes (which is connected to Pin B) is applied “High” voltage. Therefore, Droplet 2 has to be moved in the direction indicated by the arrow, no matter where the scheduled movement direction points. In this case, the unwanted movement of the droplet may occur. The number of all possible concurrent movements for the droplet pair is  $1 + 3 \times 3 = 10$ . To avoid unwanted movement of droplets that may be located on any two arbitrary positions of the layout, the pin-assignment configurations discussed in this case should be forbidden.

(3.b) Pin A connects to  $E_{1C}$  and Pin B connects to  $E_{2C}$  (or vice versa): Assume

Pin A is also connected to electrode  $E_{2L} \in \text{CEG}_2$ , and Pin B is also connected to electrode  $E_{1L} \in \text{CEG}_1$ . Then  $\text{CEG}_{2L}$  denotes the control electrode group whose central electrode is  $E_{2L}$ . Since  $E_{2C}$  and  $E_{2L}$  are two adjacent electrodes, it is easy to see that  $E_{2C} \in \text{CEG}_{2L}$ . Therefore,  $\text{CEG}_1$  and  $\text{CEG}_{2L}$  share two pins and their central electrodes are both controlled by Pin A. The pin-assignment configuration for  $\text{CEG}_1$  and  $\text{CEG}_{2L}$  is the same as the configuration discussed in Case (3.a), and may lead to the unwanted movement of a droplet. The pin-assignment configurations discussed in this case should also be forbidden.

(3.c) Pin A and B are connected to neither  $E_{1C}$  nor  $E_{2C}$ : An example is shown in Figure 6.2(e). Suppose Droplet 1 and Droplet 2 are scheduled to move in the directions indicated by the arrows. For the movement of Droplet 1, the control voltages applied to Pins A, B, C, D, and E should be set as Low, High, Low, Low, and Low, respectively. Similarly, for the movement of Droplet 2, the control voltages on Pins A, B, F, G, and H should be set as High, Low, Low, Low, and Low, respectively. Therefore, the status of Pin A and Pin B corresponding to the movements of Droplet 1 and Droplet 2 are different. To avoid a conflict, Droplet 1 and Droplet 2 must be moved in different clock cycles. Assume that Droplet 1 is moved first; a “High” voltage will be applied to Pin B. To make Droplet 2 stay at its current position, a “High” voltage will also be applied to the electrode under Droplet 2. Therefore, for the pin-assignment configuration discussed in this case, one droplet can be moved freely, while the other droplet may have to stall on the current electrode. The number of all possible concurrent movements for the droplet pair is  $1+1+2 \times 2 = 6$ . Note that even though droplets will not undergo unwanted movement or splitting in this case, the number of possible movements is relatively low. This shows that the flexibility of droplet movement in this case is rather limited, hence we should avoid such a pin-assignment.

(3.d) Pin A is connected to  $E_{1C}$  or  $E_{2C}$ , and Pin B is neither connected to  $E_{1C}$

nor  $E_{2C}$ : Without loss of generality, we assume that Pin A is connected to  $E_{1C}$ . An example is shown in Figure 6.2(f). In this pin-assignment configuration, unwanted movement or splitting of droplets will not occur. The number of possible concurrent movements in this case is  $1 + 6 = 7$ , as explained below. Droplet 1 and Droplet 2 can be moved to the electrodes controlled by Pin B concurrently (1 possible concurrent movement); Droplet 1 can be moved to the electrodes controlled by Pins E, C, and D; while Droplet 2 can be moved to the electrodes controlled by Pins G and H ( $3 \times 2$  possible concurrent movements).

(3.e) Pin B is connected to  $E_{1C}$  or  $E_{2C}$ , and Pin A is neither connected to  $E_{1C}$  nor  $E_{2C}$ : This case can be analyzed in the same way as Case (3.d). The number of all possible concurrent movements for the droplet pair is 7.

Based on the above analysis, we conclude that when two CEGs share two pins, for Case (3.a) and Case (3.b), droplets may undergo unwanted movement. For Cases (3.c)~(3.e), unwanted movement or splitting of droplet will not occur. However, the number for possible concurrent movements is no more than 7. Comparing with a direct-addressing biochip, the flexibilities of droplet movements in Cases (3.c)~(3.e) are relatively low. Hence we ensure that such pin assignments are not considered in the biochip designs studied in this chapter.

Based on the above discussion, we obtain the following lemma, which provides a necessary and sufficient condition for the acceptance of any arbitrary pin-assignment configuration with two droplets on two arbitrary positions of the biochip. The goal is to prevent unwanted splitting or movement of droplets, and also guarantee significant flexibility for the concurrent movement of droplets.

**Lemma 6.2.1.** *Consider an electrode array with any arbitrary pin-assignment configuration. Suppose two droplets are located at any two arbitrarily chosen electrodes. The following constraints are necessary and sufficient to avoid any unwanted splitting*

or movement of droplets, to permit the movement of each droplet along any feasible direction in the array, and to guarantee that the number of possible concurrent movements is no less than 10:

*Constraint 1: Any two electrodes in the same control electrode group cannot be connected to the same control pin.*

*Constraint 2: Any two non-overlapping electrode groups cannot share more than one pin.*

*Proof:* The necessity of Constraint 1 can be proven by *reductio ad absurdum*. We assume that two electrodes in the same CEG share one pin. Suppose unwanted splitting and movement of droplets can be avoided, and each droplet can be moved along any feasible direction in the array. From the discussion of Cases (1.a)~(1.c), we can find that droplets may undergo unwanted splitting or movement, or the movement of a droplet along some directions can never be achieved. Hence we have reached a contradiction.

The necessity of Constraint 2 also can be proven by *reductio ad absurdum*. We assume that two CEGs share  $k$  control pins, where  $k > 1$ . From the discussion of Cases (3.a)~(3.e), we find that in some cases, droplets may undergo unwanted splitting or movement. In every other case, the number of possible concurrent movements for the two droplets is no more than 7. The sufficiency of Constraint 1 and Constraint 2 is proven based on the analysis for Cases (2.a)~(2.c). When Constraint 1 and Constraint 2 are satisfied, unwanted movement or splitting of droplets will not occur. The number of all possible concurrent movements for the droplet pair is at least 10, and each droplet can be moved along any feasible direction in the array.

Based on the above discussion, the necessity and sufficiency of Constraint 1 and Constraint 2 in Section 6.2.1 are proven.  $\square$

Note that Constraint 1 and Constraint 2 also ensure that when one droplet is

split, the other droplet does not undergo any unwanted splitting or movement. Since the movement of a droplet from one electrode to its adjacent electrode is the basic operation for dispensing, mixing, and transportation operations, Constraint 1 and Constraint 2 can ensure the maximum degree of freedom for any concurrent fluid-handling operations involving any two droplets.

### 6.3 ILP model for pin-assignment

In this section, we develop an integer linear programming (ILP) model to optimally solve the pin-assignment problem. As explained later, the model forms the basis for evaluating heuristic solutions. On an  $M \times N$  electrode array, let  $x_{i,m,n}$  be a binary variable defined as below.

$$x_{i,m,n} = \begin{cases} 1, & \text{if Pin } i \text{ is connected to the electrode at the} \\ & m^{\text{th}} \text{ row and } n^{\text{th}} \text{ column of the array} \\ 0, & \text{otherwise} \end{cases}$$

where  $1 \leq i \leq L$ . The parameter  $L$  is the maximum possible index for the number of control pins and the value of  $L$  can be set to an easily-determined loose upper bound.

The index of the control pin connected to the electrode at the  $m^{\text{th}}$  row and  $n^{\text{th}}$  column of the array is defined as  $P_{m,n}$ . It can be expressed as  $P_{m,n} = \sum_{i=1}^L i \cdot x_{i,m,n}$ . The total number of pins that are assigned to electrodes is equal to the maximum value of  $P_{m,n}$  (where  $1 \leq m \leq M$  and  $1 \leq n \leq N$ ). Hence, the total number of pins assigned to electrodes in the layout (i.e.,  $N_{\text{tol}}$ ) can be written as:  $N_{\text{tol}} = \text{Max}_{1 \leq i \leq L, 1 \leq m \leq M, 1 \leq n \leq N} \{i \cdot x_{i,m,n}\}$ . Since the target of the ILP model is to derive a feasible pin-assignment configuration that has the minimum number of control pins. The objective function of the ILP model for a pin-limited digital microfluidic biochip is defined as:

$$\text{minimize: } N_{\text{tol}} \tag{6.1}$$

Next we map Constraint 1 and Constraint 2 of Section 6.2.1 into inequalities of the ILP model. The electrode group whose central electrode is at the  $m^{\text{th}}$  row and  $n^{\text{th}}$  column of the array is written as  $EG_{m,n}$ . In any electrode group  $EG_{m,n}$ , the number of electrodes that are connected to any Pin  $i$  is defined as  $N_{i,m,n}$ , which can be written as:

$$N_{i,m,n} = x_{i,m,n} + x_{i,m+1,n} + x_{i,m-1,n} + x_{i,m,n+1} + x_{i,m,n-1}. \quad (6.2)$$

Therefore, Constraint 1 of Section 6.2.1 can be expressed as the following set of constraints:  $N_{i,m,n} \leq 1, \forall 1 \leq i \leq L, 1 \leq m \leq M, 1 \leq n \leq N$ .

The Constraint 2 of Section 6.2.1 can be further derived as follows. For two electrode groups  $EG_{m,n}$  and  $EG_{m+p,n+q}$ , if  $p$  and  $q$  are integers and  $|p| + |q| \geq 3$ , then these two electrode group are non-overlapping. Based on the definition given by Equation 6.2, for  $EG_{m+p,n+q}$ , the number of electrodes that are connected to Pin  $i$  is  $N_{i,m+p,n+q}$ . For  $EG_{m,n}$  and  $EG_{m+p,n+q}$ , the numbers of electrodes that are connected to another Pin  $j$  are written as  $N_{j,m,n}$  and  $N_{j,m+p,n+q}$ , respectively. Assume that Constraint 2 in Section 6.2.1 is violated, and  $EG_{m,n}$  and  $EG_{m+p,n+q}$  share Pin  $i$  and Pin  $j$ . Then there will be:  $N_{i,m,n} \geq 1, N_{i,m+p,n+q} \geq 1, N_{j,m,n} \geq 1$ , and  $N_{j,m+p,n+q} \geq 1$ . Therefore, when Constraint 2 is violated, there must exist integers  $i, j, m, n, p$ , and  $q$ , such that  $N_{i,m,n} + N_{i,m+p,n+q} + N_{j,m,n} + N_{j,m+p,n+q} \geq 4$ . In order to make sure Constraint 2 is not violated, we have the following inequalities:

$$N_{i,m,n} + N_{i,m+p,n+q} + N_{j,m,n} + N_{j,m+p,n+q} \leq 3, \\ \forall 1 \leq i \neq j \leq L, 1 \leq m \leq M, 1 \leq n \leq N, |p| + |q| \geq 3. \quad (6.3)$$

The objective function given by (1) can be linearized using standard techniques. This completes the ILP model for optimization. For the  $M \times N$  microfluidic array, the number of CEGs is  $MN$ . The number of inequalities derived from Constraint 1 and Constraint 2 are  $O(MNL)$  and  $O(M^2N^2L^2)$ , respectively. Thus for the ILP

FIGURE 6.3: Pseudocode for the construction of the pin-assignment configuration using a greedy algorithm.

model introduced above, the number of variables in the ILP model is  $O(MNL)$ , and the number of constraints is  $O(M^2N^2L^2)$ . It is important to note that, since  $L$  is a loose upper bound for the number of pins, we have  $L = O(MN)$ . The ILP model is clearly not scalable for a large problem instance; nevertheless, we use it to evaluate the quality of the heuristic solution that we design in the next section.

## 6.4 Heuristic optimization method

The ILP model introduced in Section 6.3 has high computational complexity and the CPU time is unacceptable for large biochips. In this section, we develop a heuristic algorithm to generate a pin-assignment configuration efficiently; the pseudocode for this algorithm is shown in Figure 6.3. The algorithm includes two phases; the first phase is to establish a lower bound on the number of pins, and the second phase is to construct the pin-assignment configuration in a greedy fashion. In order to improve the efficiency of the greedy algorithm, we propose a mapping from a pin-assignment configuration to an undirected graph, and then we use the graph to ascertain whether the pin-assignment configuration is a feasible solution. A lower bound on the number of pins from the graph model is also described.

For simplicity, we define two operators. First, the pin-assignment configuration is defined as the operator  $\mathcal{C}$ , which is a mapping from the set of all electrodes on the chip ( $E^*$ ) to the set of pins that are assigned to the electrodes ( $P$ ).

$$\mathcal{C} : E^* \rightarrow P \quad (6.4)$$

For example, Figure 6.4(a) shows the coordinate locations for the electrodes and Figure 6.4(b) shows the corresponding pin-assignment configuration. Here, the electrode at position  $(i, j)$  is represented by  $E_{(i,j)}$ , and  $E^* = \bigcup_{i,j} E_{(i,j)}$ . When the operator  $\mathcal{C}$  is applied to  $E_{(1,1)}$ , we get  $\mathcal{C}(E_{(1,1)}) = \text{Pin A}$ .

For any electrode  $E \in E^*$ , we can virtually place a droplet on this electrode and obtain the CEG, referred as  $E_{group}$  for this virtual droplet. By taking any two elements from  $E_{group}$ , we can get an unordered pair of electrodes. The set that consists of all such electrode pairs is represented by  $E_{pair}$ .

Next, the operator  $\Phi$  is defined as a mapping from the set of electrodes  $E^*$  to the

FIGURE 6.4: (a) Coordinate locations for the electrodes; (b) pin-assignment for the electrodes; graphs corresponding to electrode (c)  $E_{(1,2)}$ ; (d)  $E_{(1,3)}$ ; (e)  $E_{(2,3)}$ ; and (f)  $E_{(3,3)}$ .

set of electrode pairs  $E_{pair}$ .

$$\Phi : E^* \rightarrow E_{pair} \quad (6.5)$$

For example, as shown in Figure 6.4(a), when the operator  $\Phi$  is applied to  $E_{(1,3)}$ ,

the following mapping is obtained:

$$\Phi(E_{(1,3)}) = \{(E_{(1,3)}, E_{(1,2)}), (E_{(1,3)}, E_{(2,3)}), (E_{(1,2)}, E_{(2,3)})\}.$$

Based on operators  $\mathcal{C}$  and  $\Phi$  defined above, for any electrode  $E_{(i,j)}$  on the layout, a graph  $G_{(i,j)}$  can be constructed as follows. First, a droplet is placed virtually on the electrode  $E_{(i,j)}$  and the corresponding CEG ( $E_{group(i,j)}$ ) is obtained. By applying operator  $\mathcal{C}$  to each element of  $E_{group(i,j)}$ , we get the CPG ( $P_{group(i,j)}$ ) that corresponds to this virtual droplet. Each pin in  $P_{group(i,j)}$  is mapped to a node in  $G_{(i,j)}$ .

By applying operator  $\Phi$  on  $E^*$ , the set of electrode pairs  $E_{pair(i,j)}$  can be derived. For each electrode pair  $(E_x, E_y)$  in  $E_{pair(i,j)}$ , we apply operator  $\mathcal{C}$  to it and get the corresponding pin pair  $(P_x, P_y)$ , and add an edge between the two nodes that represent  $P_x$  and  $P_y$  in the graph. This edge is labeled as  $Link_{(E_x, E_y)}$ . Since  $(E_x, E_y)$  is an unordered pair, we consider the edges with labels  $Link_{(E_x, E_y)}$  and  $Link_{(E_y, E_x)}$  as the same edge, i.e., we do not distinguish between them.

In this way, a one-to-one mapping from the set  $E_{pair(i,j)}$  to the edges in  $G_{(i,j)}$  is defined. Figures 6.4(c)-(f) show graphs  $G_{(1,2)}$ ,  $G_{(1,3)}$ ,  $G_{(2,3)}$ , and  $G_{(3,3)}$ , which correspond to electrodes  $E_{(1,2)}$ ,  $E_{(1,3)}$ ,  $E_{(2,3)}$ , and  $E_{(3,3)}$  in Figure 6.4(a), respectively.

If two or more elements in the CEG of  $E_{(i,j)}$  share the same control pin, as in the case of electrode  $E_{(2,3)}$  shown in Figure 6.4(a), graph  $G_{(i,j)}$  will contain cyclic edges, and there will be multiple edges between certain pairs of distinct nodes. The graph  $G_{(2,3)}$  corresponding to electrode  $E_{(2,3)}$ , which is a multigraph, is shown in Figure 6.4(e).

Based on above examples, we conclude that  $G_{(i,j)}$  is a complete graph if Constraint 1 in Lemma 6.2.1 is satisfied (i.e., the elements in the CEG of  $E_{(i,j)}$  are assigned to different pins). Hence the number of edges in the graph  $G_{(i,j)}$  can be derived from the number of nodes in  $G_{(i,j)}$  (i.e., the number of elements in the corresponding CEG).

For a given pin-assignment configuration, let the set of electrodes be defined as

FIGURE 6.5: (a) The *union* of graphs  $G_{(1,2)}$  and  $G_{(1,3)}$ ; (b) the *union* of graphs  $G_{(1,2)}$  and  $G_{(3,3)}$ . The graphs  $G_{(1,2)}$ ,  $G_{(1,3)}$ , and  $G_{(3,3)}$  are shown in Figure 6.4(c), Figure 6.4(d), and Figure 6.4 (f), respectively.

$E_{layout}$ . By virtually placing a droplet on electrode  $E_x \in E_{layout}$ , the graph  $G_{E_x}$  for any electrode can be derived. The graph for the pin-assignment configuration, which is written as  $G_{layout}$ , is defined as the *union* of all  $G_{E_x}$  ( $E_x \in E_{layout}$ ), i.e.,  $G_{layout} = \bigcup_{E_x \in E_{layout}} G_{E_x}$ , where the set of nodes in  $G_{layout}$  is obtained by applying the union operation to the set of graphs in  $G_{E_x}$ ,  $\forall E_x \in E_{layout}$ . Edges with the same label are considered as the same edge in the union graph [126].

Next, we use two examples to illustrate the *union* of two graphs. Figure 6.5(a) shows the *union* of graphs  $G_{(1,2)}$  and  $G_{(1,3)}$ . Graphs  $G_{(1,2)}$  and  $G_{(1,3)}$  can be found in Figure 6.4(c) and Figure 6.4(d), respectively. Note that the edge between nodes B and C in  $G_{(1,2)}$  and the edge between nodes B and C in  $G_{(1,3)}$  are both labeled as  $Link_{(E_{(1,2)}, E_{(1,3)})}$ , hence they are considered to be the same edge in the merged graph. In the merged graph  $G_{(1,2)} \cup G_{(1,3)}$ , there is only one edge  $Link_{(E_{(1,2)}, E_{(1,3)})}$  between nodes B and C. By checking the number of edges between each pair of nodes, we find that the merged graph is a simple graph.

Figure 6.5(b) is the *union* of graphs  $G_{(1,2)}$  and  $G_{(3,3)}$ . Graphs  $G_{(1,2)}$  and  $G_{(3,3)}$  can be found in Figure 6.4(c) and Figure 6.4(f), respectively. Note in graph  $G_{(1,2)}$  the edge between nodes A and C is labeled as  $Link_{(E_{(1,1)}, E_{(1,3)})}$ , and in graph  $G_{(3,3)}$

the edge between nodes A and C is labeled as  $Link_{(E_{(3,2)}, E_{(3,3)})}$ . Therefore the merged graph  $G_{(1,2)} \cup G_{(3,3)}$  has two edges between nodes A and C, i.e.,  $G_{(1,2)} \cup G_{(3,3)}$  is a multigraph.

The following lemma results from the structure of  $G_{layout}$  and the acceptability of the pin-assignment (Section 6.2.1). Note that depending on the mapping of control pins to electrodes,  $G_{layout}$  may be a simple graph (no self-loop and no more than one edge between any two distinct nodes) or a multigraph (either with a self-loop or more than one edge between some pairs of nodes) [126].

**Lemma 6.4.1.** *A pin-assignment configuration satisfies Constraint 1 and Constraint 2 in Section 6.2.1 if and only if the graph  $G_{layout}$  is a simple graph.*

*Proof:* First we assume that Constraint 1 in Lemma 6.2.1 is violated. Thus, an electrode group  $E_{group(x)}$  exists in which two elements share the same control pin. According to the definition of edges for  $G_{E_x}$ , there will be cyclic edges and multiple edges between two nodes. Thus  $G_{E_x}$  is a multigraph. Since  $G_{E_x}$  is a subgraph of  $G_{layout}$ ,  $G_{layout}$  is also a multigraph.

We next assume that Constraint 2 in Lemma 6.2.1 is violated. Thus two non-overlapping CEGs  $E_{group1}$  and  $E_{group2}$  exist, and their corresponding CPGs share more than one common pin. Assume the graph derived from  $E_{group1}$  and  $E_{group2}$  are  $G_1$  and  $G_2$ , respectively. Suppose  $E_{x_1} \in E_{group1}$  and  $E_{x_2} \in E_{group2}$  are both connected to pin X, and  $E_{y_1} \in E_{group1}$  and  $E_{y_2} \in E_{group2}$  are both connected to pin Y. According to the definition of the one-to-one mapping from the set of electrode pairs to edges in the graph, electrode pair  $\{E_{x_1}, E_{y_1}\}$  is mapped to an edge between the nodes that represent pin X and pin Y. The label of this edge is  $Link_{(E_{x_1}, E_{y_1})}$  (or  $Link_{(E_{y_1}, E_{x_1})}$ ). Electrode pair  $\{E_{x_2}, E_{y_2}\}$  is mapped to an edge between the nodes that represent pin X and pin Y. The label of this edge is  $Link_{(E_{x_2}, E_{y_2})}$  (or  $Link_{(E_{y_2}, E_{x_2})}$ ). Based on the definition of the *union* of two graphs, when  $G_1$  and  $G_2$  are merged to  $G_1 \cup G_2$ ,

there will be two edges with different labels between the nodes that represent pin X and pin Y. Thus  $G_1 \cup G_2$  is a multigraph. Since  $G_1 \cup G_2$  is a subgraph of  $G_{layout}$ , we can conclude that  $G_{layout}$  also is a multigraph.

According to the definition of  $G_{layout}$ , it is easy to see that if it is a simple graph, then the pin-assignment configuration satisfies Constraint 1 and Constraint 2.  $\square$

For any given layout, according to its shape, we can estimate a lower bound on the number of control pins needed to avoid pin-actuation conflicts for any target application.

Here we show two instances on the calculation of the lower bound of the number of control pins.

**Theorem 6.4.2.** *Consider an  $m \times n$  digital microfluidic array. Then suppose a pin-assignment configuration with  $M$  pins exists, such that Constraint 1 and Constraint 2 in Section 6.2.1 are satisfied. A lower bound on  $M$  is given by:*

$$\binom{M}{2} \geq 6mn - 5m - 5n + 2.$$

For a  $m \times n$  electrode array, and for any electrode  $E_{(i,j)}$  in this array, since its corresponding graph  $G_{(i,j)}$  is a complete graph, the number of edges can be derived from the number of elements in the CPG. For different positions of the electrodes, the numbers of elements in CPG are different. Thus we calculate the number of edges  $G_{layout}$  by classifying electrode into three categories according to their positions, as shown in Figure 6.6(a).

The first category includes the electrodes located at the corner of the array and the corresponding graph is shown in Figure 6.6(b). For each graph, there are three nodes and the number of edges is  $\binom{3}{2}=3$ . Since the number of such electrodes in the  $m \times n$  array is 4, we get 4 graphs with 3 edges. The second category includes the electrodes located at four sides but not the corners of the array, and the corresponding

FIGURE 6.6: (a) Three categories of electrodes and the graphs correspond to electrodes of (b) the first category (c) the second category (c) the third category.

graph is shown in Figure 6.6(c). For each graph, there are four nodes and the number of edges is  $\binom{4}{2}=6$ . Since the number for such electrodes is  $2(m+n-4)$ , we have  $2(m+n-4)$  graphs with 6 edges. The third category includes the electrodes located within the array and the corresponding graph is shown in Figure 6.6(d). For each graph, there are five nodes and the number of edges is  $\binom{5}{2}=10$ . Since the number of such electrodes is  $(m-2) \times (n-2)$ , we will get  $(m-2) \times (n-2)$  complete graphs with 10 edges.

On the other hand, the number of edges that are contained in two graphs is  $(m-1) \times n + (n-1) \times m + 2 \times (m-1) \times (n-1)$ . Therefore, using the principle of inclusion/exclusion, we set the total number of edge in the graph  $G_{layout}$  to be:

$$\begin{aligned}
 N_{edge} &= 4 \times 3 + 12(m+n-4) + 10(mn-2m-2n+4) \\
 &\quad - [(m-1)n + (n-1)m] - 2 \times (m-1) \times (n-1) \\
 &= 6mn - 5m - 5n + 2
 \end{aligned}$$

FIGURE 6.7: An  $m \times n$  outlined rectangle.

According to Lemma 6.4.1, if the pin-assignment configuration satisfies Constraint 1 and Constraint 2, then graph  $G_{layout}$  is a simple graph. Assume that there are  $M$  control pins in the pin-assignment configuration. The number of nodes in graph  $G_{layout}$  is equal to  $M$ . The maximum number of edges in the simple graph  $G_{layout}$  that has  $M$  nodes is given by:

$$N_{edge\_max} = \binom{M}{2} = \frac{M \times (M-1)}{2}$$

Finally, we derive the desired lower bound in the number of control pins. Since  $N_{edge\_max}$  is an upper limit on the number of edges in a graph, we have the inequality  $N_{edge\_max} \geq N_{edge}$ . □

Based on Theorem 6.4.2, we have following corollary:

**Corollary 6.4.3.** *For large values of  $m$  and  $n$ , the lower bound on the number of control pins can be approximated as  $M_{min} \approx 2\sqrt{3mn}$ , and if  $m = n = t$ , we get  $M_{min} \approx 2\sqrt{3}t$ . In other words, the number of pins is  $\Omega(\sqrt{N})$  when the total number of electrodes in the array is  $N$ .*

Next we calculate the lower bound for the number of control pins required by an  $m \times n$  outlined rectangular layout. The layout is shown in Figure 6.7, and the outlined rectangular array is used extensively in commercial biochips [123][124]. For the outlined rectangular array, we have the following theorem:

**Theorem 6.4.4.** *A lower bound on the number of control pins in the  $m \times n$  outlined rectangle is given by following inequality:*

$$\binom{M}{2} \geq 4m + 4n - 8.$$

*Proof:* For this layout, there are  $(2(m+n)-4)$  CEGs in total and each CEG has three electrodes. When we map the layout to the graph model, we get  $(2(m+n)-4)$  complete graphs, and each graph has three nodes and three edges. Some edges are contained in more than one sub-graph. The number of edges that are contained in two graphs is  $(2 \times (n-1) + 2 \times (m-1))$ . Therefore, by using the principle of inclusion/exclusion, we get the total number of edges in the graph  $G_{layout}$  as:

$$\begin{aligned} N_{edge} &= 3 \times (2(m+n)-4) - (2 \times (n-1) + 2 \times (m-1)) \\ &= 4m + 4n - 8 \end{aligned}$$

According to Lemma 6.4.1, if the pin-assignment configuration satisfies Constraint 1 and Constraint 2, then graph  $G_{layout}$  is a simple graph. Assume that there are  $M$  control pins in the pin-assignment configuration, the number of nodes in graph  $G_{layout}$  is equal to  $M$ . The maximum number of edges  $N_{edge\_max}$  in the simple graph  $G_{layout}$ , which has  $M$  nodes, is given by:

$$N_{edge\_max} = \binom{M}{2} = \frac{M \times (M-1)}{2}$$

Finally, we derive the desired lower bound in the number of control pins for the outlined rectangular layout. Since  $N_{edge\_max}$  is an upper limit on the number of edges in a graph, we have the inequality  $N_{edge\_max} \geq N_{edge}$ . □

Based on Theorem 6.4.4, we have following corollary:

**Corollary 6.4.5.** *For large values of  $m$  and  $n$ , the lower bound on the number of control pins can be approximated as  $M_{min} \approx 2\sqrt{m+n}$ , and if  $m = n = t$ , we get*

$M_{min} \approx 2\sqrt{2t}$ . In other words, the number of pins is  $\Omega(\sqrt{N})$  when the total number of electrodes in the array is  $N$ .

For an electrode array that has other shapes, the number of control pins can be lower-bounded in a similar manner.

Let us now return to the pseudocode shown in Figure 6.3. In the first phase, we determine the lower bound  $N_L$  on the number of pins, and then initialize the set of available pins (which is written as *PinAvailable* in Figure 6.3) as {Pin 1, Pin 2, ..., Pin  $N_L$ }. In the second phase, we set an index number for each electrode on the layout by numbering the electrodes one by one, from the electrode on the upper-right corner to the lower-left corner. Then an electrode  $E_R$  is randomly selected as the “seed” of the pin-assignment process, and Pin 1 is assigned to  $E_R$ . The set of electrodes whose control pins have been determined is written as “ElectrodesAlreadyAssigned” (as shown in Figure 6.3). The graph corresponding to the pin-assignment configuration of ElectrodesAlreadyAssigned is written as  $G_{EAA}$ .

Then electrode  $E_R$  is the first element that is added into the set ElectrodesAlreadyAssigned. The pin-assignment configuration for the layout is constructed electrode-by-electrode around the seed  $E_R$ . In each step, we locate all the neighboring electrodes of ElectrodesAlreadyAssigned and sort out the electrodes to identify the one that has the minimum index number. The electrode with the minimum index number is written as  $E_{neighbor}$  as shown in Figure 6.3. Then, starting from Pin 1 and proceeding through Pin  $N_L$ , we search for the control pin that can be assigned to  $E_{neighbor}$  to obtain a feasible pin-assignment solution. Here are the detailed steps of the searching process.

Each time we virtually assign a control pin to  $E_{neighbor}$ , and update  $G_{EAA}$  by doing the union of the original  $G_{EAA}$  with the graph that corresponds to the new electrode. Then we determine whether the updated  $G_{EAA}$  is a simple graph. Based

on Lemma 6.4.1, if  $G_{\text{EAA}}$  is a simple graph, then we have expanded the feasible local solution successfully and  $E_{\text{neighbor}}$  will be added into the set *ElectrodesAlreadyAssigned*, as shown in Figure 6.3. Otherwise, we will change the pin that is assigned to  $E_{\text{neighbor}}$ .

If none of the pins in set *PinAvailable* can be assigned to  $E_{\text{neighbor}}$ , a new pin is added into *PinAvailable*, and this newly added pin is assigned to  $E_{\text{neighbor}}$ . By repeating the above procedure, the set *ElectrodesAlreadyAssigned* can be expanded step-by-step until it covers the whole layout. When we assign pins to the newly-added electrode, the *complement* of the graph  $G_{\text{EAA}}$ , referred to as  $H_{\text{EAA}}$ , is used to reduce the search scope. All the pins corresponds to isolated nodes in  $H_{\text{EAA}}$  are “unavailable pins” and they cannot be assigned to  $E_{\text{neighbor}}$ .

Assume that the number of electrodes on the array is  $\mathcal{N}$  and the number of pins assigned to the electrodes is  $\mathcal{P}$ . The computing complexity for checking whether  $G_{\text{EAA}}$  is a simple graph is  $O(\mathcal{P}^2)$ . Each time when we assign a pin to  $E_{\text{neighbor}}$ , we have to verify whether  $G_{\text{EAA}}$  is a simple graph. Thus for the worst case, the computational complexity of assigning a pin to  $E_{\text{neighbor}}$  is  $O(\mathcal{P}^3)$ . Since all electrodes are added step-by-step to the set *ElectrodesAlreadyAssigned*, the overall computational complexity of the heuristic procedure is  $O(\mathcal{P}^3\mathcal{N})$ .

The heuristic algorithm can therefore quickly generate a feasible pin-assignment configuration, and for each given array layout, the number of control pins derived by the heuristic algorithm can be used as the upper bound on the number of control pins. For  $n \times n$  rectangular layouts and  $n \times n$  outlined rectangular layouts, the lower bounds for the number of pins derived from the theoretical analysis and the upper bounds for the number of pins derived from the heuristic algorithm are shown in Figure 6.8.

## 6.5 Manipulation of large droplets

Bioassay benchmarks used to evaluate biochip design automation methods in the literature make the assumption that all input and output droplets of mixing/dilution operations are  $1\times$  droplets [35][73]. However, with recent advances in fabrication technology, digital microfluidic biochips can now transport  $2\times$  and even larger droplets; the transportation of larger droplets requires higher actuation voltages [127]. Some newly developed bioassay protocols for lab-on-chip include the manipulation of  $2\times$  droplets. For example, to capture antibodies, a  $1\times$  blood droplet needs to be mixed with a  $2\times$  droplet that contains magnetic beads in the “on-magnet in-

cubation” protocol [124]. To execute this bioassay, the biochip needs to be able to transport  $2\times$  and even larger droplets.

To move droplets with large volumes, more electrodes need to be activated at each clock cycle [128]. However, the manipulation of droplets with different volumes introduces new constraints for the design of pin-limited biochips. We discuss these details below.

#### 6.5.1 *Transportation of $2\times$ droplets*

To avoid pin-sharing conflicts, the layout of a biochip that can manipulate  $2\times$  droplets must satisfy Constraint 1 and Constraint 2 derived in Section 6.2.1. A difference here is that more pins must be actuated to manipulate large droplets, i.e., the CPG of a large droplet may contain more pins than the CPG of a  $1\times$  droplet.

As shown in Figure 6.9(a), a  $2\times$  droplet will elongate in the direction of movement [128]. Here, the CPG of the droplet movement includes Pins A, B, C, D, E, and F. To move the  $2\times$  droplet in the direction of the arrow, the signals applied to pins B and C must be set as “High”, and the signals applied to Pins A, D, E, and F must be set as “Low”. It is important to note that when the  $2\times$  droplet is moved to a different direction, the elements in the CPG of the  $2\times$  droplet are changed to Pins A, B, D, E, F, and G, as shown in Figure 6.9(b).

When we convert the CPG of a  $2\times$  droplet to its graph model, we must consider all the possible directions in which the droplet can move. An example is shown in Figure 6.10(a). The  $2\times$  droplet has two possible movement directions, i.e., Direction 1 and Direction 2. If the droplet is moved in Direction 1, the elements in its CPG are Pins A, B, C, and F. The corresponding graph model for this CPG ( $G_{D_1}$ ) is shown in Figure 6.10(b); if the droplet is moved in Direction 2, the elements in its CPG are Pins A, B, F, and G. The corresponding graph model for this CPG ( $G_{D_2}$ ) is shown in Figure 6.10(c). The graph model for the CPG of the droplet can be derived by

FIGURE 6.9: (a) To move the  $2\times$  droplet to the arrow's direction, Pins B and C must be "High", and Pins A, D, E, and F must be "Low"; (b) to move the droplet in another direction, pins F and G must be "High", and Pins A, B, D, and E must be "Low".

calculating the *union* of graphs  $G_{D_1}$  and  $G_{D_2}$ , as shown in Figure 6.10(d).

For the given pin-assignment configuration discussed in Section 6.4, let the set of electrodes be defined as  $E_{layout}$ . When considering the transportation of the  $2\times$  droplet, we can construct a graph model for the layout  $E_{layout}$  by virtually placing a  $2\times$  droplet on electrode  $E_x \in E_{layout}$ . As discussed above, when the  $2\times$  droplet is moved in different directions, the elements in the CPG are different. Note that when we design the pin-assignment configuration, we do not assume any knowledge of the position of the  $2\times$  droplets or the directions in which they must be moved in different clock cycles. Therefore,  $2\times$  droplets can be present at any position in the layout, and these  $2\times$  droplets can be moved in any non-diagonal direction. To derive the graph  $G_{E_x}$  for any electrode, we must consider all the possible directions in which the droplet can move, and obtain their corresponding graphs as explained below.

The graph for the pin-assignment configuration, which is written as  $G_{layout}$ , is defined as the *union* of all the  $G_{E_x}$  graphs, i.e.,  $G_{layout} = \bigcup_{E_x \in E_{layout}} G_{E_x}$ , where

$G_{E_x}$  is defined as:  $G_{E_x} = \bigcup \{G_{E_x D_1}, G_{E_x D_2}, \dots, G_{E_x D_D}\}$ , and  $D_1, D_2, \dots, D_D$  are the possible directions for the movement of the  $2\times$  droplet that stays on electrode  $E_x$ .

We can easily prove that, for the biochips involving the transportation of  $2\times$

FIGURE 6.10: (a) The  $2 \times$  droplet has two possible movement directions; (b)  $G_{D_1}$ : graph model of CEG corresponding to the movement in Direction 1; (c)  $G_{D_2}$ : graph model of CEG corresponding to the movement in Direction 2; (d) graph model derived by the union of  $G_{D_1}$  and  $G_{D_2}$ .

droplets, Lemma 6.4.1 can still be used as an acceptance test for feasible pin-assignment configurations. The heuristic algorithm shown in Figure 6.3 can be used for the biochip with manipulations of  $2 \times$  droplets, and similarly we can determine the upper and lower bounds for the number of control pins.

For an  $n \times n$  array, the lower bound and upper bound for the number of control pins are shown in Figure 6.11(a). For an  $n \times n$  outlined rectangular array, the lower bound and the upper bound for the number of control pins are shown in Figure 6.11(b). By comparing the lower/upper bounds on the number of control pins presented in Figure 6.8 and Figure 6.11, we can find that in order to manipulate  $2 \times$  droplets, the number of pins assigned to the biochip has to increase.

### 6.5.2 Influence of diagonal electrodes

In this subsection, we discuss the influence of diagonally adjacent electrodes on the movement of a droplet. Assume that the droplet shown in Figure 6.12(a) will be moved in the direction of the arrow, and the electrode that the droplet will be moved to is actuated. The contact line between the droplet and the actuated electrode is shown in Figure 6.12(a). According to the principle of EWOD, the total electrowetting force  $F$  applied to the droplet can be written as [128]:

$$F = f_m \cdot L \cdot \sin \alpha, \quad (6.6)$$

(a)

(b)

FIGURE 6.11: (a) Relationship between lower/upper bounds on pin-counts and the sizes of the electrode array (rectangular layouts) for biochips with  $2\times$  droplets; (b) relationship between lower/upper bounds on pin-counts and the sizes of the electrode array (outlined rectangular layouts) for biochips with  $2\times$  droplets.

where  $L$  is the diameter of the droplet, and the angle  $\alpha$  is shown in Figure 6.12(a)[128]. The parameter  $f_m$  is the driving force per unit length of the contact line [128], which is determined by the surface characteristics of the device and the actuation voltage applied to the electrode. For a given liquid in the droplet and a given biochip,  $f_m$  can be regarded as a constant [128].

For a typical EWOD device, the size of the square electrodes is  $1 \times 1$  mm. As shown in Figure 6.12(a) and Figure 6.12(c), there is a gap between the two adjacent electrodes. The gap between two adjacent electrodes in the typical EWOD device is  $20 \mu m$  [129]. So, if we set the length and width of the electrode as 1 unit length, the

FIGURE 6.12: (a) The force applied to the droplet when a non-diagonally adjacent electrode is actuated; (b) relationship between the diameter of the droplet and the force  $F$  applied to the droplet; (c) the force  $F_D$  applied to the droplet when a diagonally adjacent electrode is actuated; (d) relationship between the diameter of the droplet and  $\frac{\|F_D\|}{\|F\|}$ .

gap between electrodes is 0.02 unit length. Assume that the diameter of the droplet is  $D$  unit length, then according to Equation 6.6, the relationship between  $D$  and the force applied to the droplet is shown in Figure 6.12(b). We can find that, when the diameter of the droplet increases to 1.46 unit length, the force applied to the droplet does not increase any further.

Note that when the size of the droplet increases, it may contact diagonally adjacent electrodes as well as non-diagonally adjacent electrodes (Figure 6.12(c)). In this

case, if a non-diagonal electrode is actuated, there will be a force ( $F_D$ ) applied to the droplet in the diagonal direction. For the same droplet, the relationship between the diameter of the droplet and the value of  $\frac{\|F_D\|}{\|F\|}$  can be found in Figure 6.12(d). We can find that the value  $\frac{\|F_D\|}{\|F\|}$  increases as the diameter of the droplet increases. When the diameter of the droplet increases to 1.78 unit length, we have  $\|F_D\| = \|F\|$ . This means that, for a “large” droplet, the influence of its diagonal electrodes can no longer be ignored. In this case, when we move a droplet from one electrode to its non-diagonally adjacent electrode, all the diagonal electrodes of the droplet must be applied “Low” voltage. Otherwise these diagonal electrodes of the droplet will influence the movement of the droplet. In this case, we note that biochips that are required to manipulate a large droplet must satisfy Constraint 1 and Constraint 2 in Section 6.2.1, with the difference that the CEG includes all the nine electrodes in contact with the droplet.

## 6.6 Scheduling of fluid-handling operations

For general-purpose biochips, fluid-handling operations must be scheduled after the pins are assigned to electrodes. This is in contrast to bioassay-specific design where the scheduling precedes pin-assignment. In our work the initial schedule is derived without considering any pin constraints, and then the schedule is adjusted according to the pin-assignment configuration.

For example, when multiple fluid-handling operations are scheduled to be executed concurrently, their control signals may conflict with each other. In order to solve this problem, we must decide the order in which the fluid-handling operations will be implemented and determine the appropriate voltages to be applied to the electrodes.

Assume that we have a given initial schedule. Then at each time slot  $t$ , the posi-

tions and scheduled fluid-handling operations of all the droplets are already known. Therefore, the corresponding actuation signals that need to be applied on the pins can be easily derived. Based on the actuation signals, the set of pins that must be applied “High” signal ( $S_H(t)$ ), and the set of pins that must be applied “Low” signal ( $S_L(t)$ ) can be determined. Conflicts in the actuation of the pins can occur if and only if  $C(t) = S_H(t) \cap S_L(t) \neq \emptyset$ , i.e., the operation schedule requires some control pins to be set to “High” and “Low” at the same time. In this situation, the operation schedule must be adjusted.

An example is shown in Figure 6.13(a). Assume at time  $t = t_0$ , droplets  $D_1$ ,  $D_2$ , and  $D_3$  are scheduled to be moved in the directions indicated by the arrows, and  $D_4$  is scheduled to be split. To implement the fluid-handling operation for droplets  $D_3$ , we have the following set of pins that must be applied “High” voltage:  $S_H^{D_3}(t_0) = \{11\}$ ; to implement the fluid-handling operation for droplets  $D_4$ , we have the following set of pins that need to be applied “Low” voltage:  $S_L^{D_4}(t_0) = \{2, 11, 14\}$ . Hence we have  $S_H^{D_3}(t_0) \cap S_L^{D_4}(t_0) \neq \emptyset$ , i.e., the fluid-handling operations scheduled for droplets  $D_3$  and  $D_4$  cannot be implemented concurrently, otherwise the actuation signals for  $D_3$  may lead to unintended movement of  $D_4$ . Note that the moving and splitting of droplets are the basic operations implemented on the biochip, and other operations such as droplet dispensing and mixing can be considered as a sequence of these basic operations.

To determine the actuation signals that must be applied to the electrodes and the order in which to implement the fluid-handling operations, we map the conflict relationships of multiple droplets to a directed graph, and each droplet is mapped to a node. For two droplets  $D_A$  and  $D_B$ , if the fluid-handling operation of  $D_A$  may lead to unintended splitting or movement of  $D_B$ , then in the conflict graph, there will be a directed edge starting from the node  $D_A$  to node  $D_B$ . The operations for droplets that correspond to the nodes with zero out-degrees in the conflict graph must be first

FIGURE 6.13: (a) Droplets  $D_1$ ,  $D_2$ , and  $D_3$  are scheduled to be moved in the directions indicated by the arrows, and  $D_4$  is scheduled to be split; (b) conflict graph derived from the pin-assignment configuration and scheduled fluid-handling operations of droplets  $D_{1-4}$ .

- 
- 1: Derive initial operation schedule without considering of pin-constraints;
  - 2: Derive the sets of pins  $S_H(t)$  and  $S_L(t)$  at time  $t$ ;
  - 3: **if**  $S_H(t) \cap S_L(t)$  **then**
  - 4:   Derive the conflict graph of droplets and determine the priorities of fluid-handling operations for droplets;
  - 5:   **if** operations for set of droplets  $F(t)$  can be executed without leading to unintended splitting or movement of other droplets **then**
  - 6:     Execute fluid-handling operations for droplets in set  $F(t)$ ;
  - 7:   **else**
  - 8:     Adjust the operation schedule; // Deadlock occurs and operations need to be re-scheduled.
  - 9:   **end if**
  - 10: **else**
  - 11:   Execute fluid-handling operations concurrently based on initial scheduling.
  - 12: **end if**
- 

FIGURE 6.14: Pseudocode for determining the priorities of the movements of the droplets.

executed, as these operations will not result in unintended splitting or movement of other droplets.

Figure 6.13(b) is the conflict graph derived from the scheduled fluid-handling operations of droplets shown in Figure 6.13(a). According to the conflict graph, we can see that droplets  $D_1$  and  $D_2$  can be moved at time  $t = t_0$ , because their fluid-handling operations will not lead to unintended splitting or movement of other droplets. Droplets  $D_3$  and  $D_4$  must remain at their current positions.

Deadlock in fluid-handling operations occurs if the manipulation of any droplet may lead to unintended splitting or movement of one or more other droplets. In this case, none of the fluid-handling operations can be executed. From the conflict graph, we can find the following necessary and sufficient condition for the occurrence of deadlock.

**Lemma 6.6.1.** *Deadlock occurs at time  $t$  if and only if all the nodes in the corresponding conflict graph have non-zero out-degrees.*

*Proof:* First, assume that deadlock occurs and none of the scheduled fluid-handling operations can be executed. Hence, executing the operation of an arbitrarily-chosen droplet  $D_K$  may lead to the unintended splitting or movement for a group of other droplets  $\{D_{K_1}, D_{K_2}, \dots, D_{K_n}\}$ . Based on the definition of edges in the conflict graph, directed edges will start from the node that represents droplet  $D_K$  and go to the nodes that represent droplets  $\{D_{K_1}, D_{K_2}, \dots, D_{K_n}\}$ . The out-degree of the node that represents droplet  $D_K$  is non-zero. Since  $D_K$  is an arbitrarily-chosen droplet, we can conclude that all the nodes in the conflict graphs have non-zero out-degrees when deadlock occurs.

Next, we prove that Lemma 6.6.1 provides a sufficient condition for the occurrence of deadlock. Based on the definition of a directed edge in the conflict graph, if the out-degree for a node is non-zero, moving the droplet that is represented by the node may lead to unintended splitting or movement of other droplets. If all the nodes in the conflict graph have non-zero out-degrees, we can conclude that the manipulation of any droplet may lead to unintended splitting or movement of other droplets. Hence the deadlock occurs.

Based on the above argument, the necessity and sufficiency of the condition in Lemma 6.6.1 are proven.  $\square$

When the deadlock occurs, one or more fluid-handling operations must be re-

scheduled. Here are the details of the re-scheduling procedure. Assume that a set of operations  $S_d$  is scheduled to be implemented concurrently, and the deadlock occurs. Then an operation  $O_R$  is randomly selected from  $S_d$  and it is re-scheduled to be implemented after all the other operations in  $S_d$  are finished. Therefore, operation  $O_R$  will not have conflicts with any operations in the set  $S_d \setminus \{O_R\}$  any more. If the deadlock still exists, then another operation from  $S_d \setminus \{O_R\}$  is randomly selected and it is also re-scheduled to be implemented after all the other operations are finished. This re-scheduling process is repeatedly implemented until the deadlock no longer occurs. The existence of a schedule without the deadlock is guaranteed by the following lemma:

**Lemma 6.6.2.** *Deadlock never occurs when there are only two droplets concurrently manipulated by the proposed general-purpose pin-limited biochip.*

*Proof:* This lemma can be proven by *reductio ad absurdum*. First we assume that at time  $t = t_d$ , deadlock occurs for two droplets  $D_x$  and  $D_y$ . According to the definition of deadlock, we know the operation on  $D_x$  may lead to the unintended splitting or movement for  $D_y$ , i.e.,  $S_H^{D_x}(t_d) \cap S_L^{D_y}(t_d) \neq \emptyset$ . Then we know the operation on  $D_y$  may lead to the unintended splitting or movement for  $D_x$ , i.e.,  $S_H^{D_y}(t_d) \cap S_L^{D_x}(t_d) \neq \emptyset$ .

For each control pin of droplet  $D_x$ , it is either in the set of  $S_H^{D_x}(t_d)$  or in the set of  $S_L^{D_x}(t_d)$ . So we have  $S_H^{D_x}(t_d) \cap S_L^{D_x}(t_d) = \emptyset$ , and the control pin group of  $D_x$  can be written as  $\text{CPG}_{D_x}(t_d) = S_H^{D_x}(t_d) \cup S_L^{D_x}(t_d)$ .

Similarly, for droplet  $D_y$ , we have  $S_H^{D_y}(t_d) \cap S_L^{D_y}(t_d) = \emptyset$ , and the control pin group of  $D_y$  can be written as  $\text{CPG}_{D_y}(t_d) = S_H^{D_y}(t_d) \cup S_L^{D_y}(t_d)$ .

So we have  $\text{CPG}_{D_x}(t_d) \cap \text{CPG}_{D_y}(t_d) = (S_H^{D_x}(t_d) \cap S_L^{D_y}(t_d)) \cup (S_H^{D_y}(t_d) \cap S_L^{D_x}(t_d))$ . It is already known that  $S_H^{D_x}(t_d) \cap S_L^{D_y}(t_d) \neq \emptyset$  and  $S_H^{D_y}(t_d) \cap S_L^{D_x}(t_d) \neq \emptyset$ , we can conclude that the CPGs of droplet  $D_x$  and  $D_y$  have at least two common elements.

This is in conflict with Constraint 2 in Section 6.2.1. This completes the proof.  $\square$

Lemma 6.6.2 shows that in the worst case, we can reduce the number of concurrent fluid-handling operations to two, and deadlock will not occur. Therefore, by re-scheduling the fluid-handling operations, we can always implement the bioassay without deadlock.

The pseudocode for the scheduling algorithm based on pin-actuation sequences is shown in Figure 6.14. Note the scheduling algorithm can be applied to any pin-limited biochip, including the bioassay-specific biochips proposed in [65][130].

## 6.7 Simulation results

In this section, we present results for two commercial biochips and several laboratory prototypes.

### 6.7.1 Commercial biochips

#### **Commercial biochip for $n$ -plex immunoassay**

In an  $n$ -plex immunoassay, a sample is concurrently analyzed for  $n$  different analytes. Sample droplets are mixed with  $n$  different reagents, and the mixed product droplets are moved to the detection area which includes an optical detector [123][124]. The commercial biochip for the  $n$ -plex immunoassay consists of more than 1000 electrodes [123][124]. The layout of this biochip and the pin-assignment derived by the proposed heuristic algorithm are presented in [123].

Table 6.1 shows the comparison of the number of control pins for the existing design for the fabricated commercial biochip [35], the result derived by bioassay-specific algorithm in [35], and the result derived by the proposed heuristic method. The proposed heuristic method leads to comparable or smaller number of control pins than both [35] and the fabricated commercial biochip. Since the pin-assignment derived by the proposed method is bioassay-independent, it also provides the added

Table 6.1: Comparison of the numbers of control pins and CPU time for the existing design of the fabricated commercial biochip in [35], the results derived by bioassay-specific algorithm in [35], and the results derived by the proposed heuristic method.

	No. pins (fabricated chip [35])	No. pins (bioassay-specific method [35])	No. pins (proposed heuristic method)

CPU time	NA	130 min [131]	7.4 s

benefit of being flexible for multiple target applications.

The CPU time for designing the layout for the commercial biochip can be found in Table 6.1. The existing pin-assignment configuration is derived manually, so it does not have CPU time [131]. The CPU time needed to generate the pin-assignment in [131] is 130 minutes while the CPU time is reduced to 7.4 s for the proposed heuristic algorithm.

### Commercial biochip for PCR bioassay

We next apply the proposed algorithm to the commercial biochip for PCR bioassay [35][131]. The chip consists of over 1000 electrodes [35][131]. The layout for the complete chip and the existing pin-assignment in the fabricated biochip (14 pins) can be found in [35][131]. Table 6.2 compares the number of control pins for the existing design for the fabricated commercial biochip in [35], the number of pins derived by bioassay-specific algorithm in [35], and the number of pins derived by the proposed heuristic method. Similar with the results of  $n$ -plex immunoassay chip, the CPU time of the proposed heuristic algorithm is 3.5 s, while the CPU time needed for generating the pin-assignment in [131] is 320 minutes.

Table 6.2: Comparison of the numbers of control pins and CPU time for the existing design of the fabricated commercial biochip in [124][35], the results derived by bioassay-specific algorithm in [35], and the results derived by the proposed heuristic method.

	No. pins (fabricated chip [35])	No. pins (bioassay-specific method [35])	No. pins (proposed heuristic method)
Routing region	7	6	6
Reaction region	14	10	14
Detection region	11	8	10
Total No. of pins	32	24	30
CPU time	NA	320 min [131]	3.5 s

### 6.7.2 Experimental biochips

Next we apply the pin-assignment algorithm to the layouts of four laboratory prototypes described in [65], namely a multiplexed assay biochip, a PCR biochip, a protein dilution biochip, and a multifunction biochip. These layouts have subsequently been incorporated in commercial chips [14]. Their pin-assignment configurations are shown in Figure 6.15.

First we compare the number of pins and bioassay completion time between the proposed general-purpose biochips and other biochips, which include the cross-referencing biochip in [37], the bioassay-specific biochips in [65] and [130], and the direct-addressing biochips. We implemented the ILP-based design method of [130] to obtain a complete set of simulation results. The simulation results are presented in Table 6.3.

Note that both the cross-referencing biochip in [37] and the proposed general-purpose biochip are bioassay-independent. When we map bioassays to bioassay-independent chips, droplet operations are scheduled after the pin-assignment configuration is determined. Therefore, the operation schedule and routing pathways are more flexible, and they can be adjusted according to the requirements of bioas-

FIGURE 6.15: Pin-assignment configurations for (a) multiplexed assay chip; (b) PCR chip; (c) protein dilution chip; (d) multi-functional chip.

says. Table 6.3 shows that the proposed method can achieve fewer number of pins and shorter execution time, compared with that cross-referencing biochips in [37]. The proposed general-purpose biochip can greatly reduce the number of control pins with only a slight increase in the bioassay completion time, compared with the direct-addressing biochips.

In order to compare the proposed method with the bioassay-specific biochips in [65], we first derive the synthesis results of bioassays without considering pin-assignment configurations. The initial synthesis results can be derived from synthesis tools such as [83][132][133]. Then the operations schedules are adjusted based on the signals applied to pins, as introduced in Section 6.6. Table 6.3 shows that, the proposed method can achieve fewer number of control pins and shorter execution time for multiplexed bioassay and protein dilution bioassay, compared with the bioassay-specific biochips in [65].

In the following discussion, the multiplexed assay biochip, PCR bioassay biochip, protein dilution biochip, and the multi-function biochip presented in Figure 6.15 are referred to as Chips 1–4; these four bioassay-specific biochips designed in [65] are referred to as Chips  $A - D$ ; and these four biochips derived by ILP-based pin-count aware design in [130] are referred to as Chips  $E - G$ .

By executing multiplexed bioassay, PCR bioassay, and protein dilution bioassay on Chips 1–4, we can evaluate the flexibility of the proposed general-purpose biochip. The completion times of these bioassays can be found in Table 6.4. Note even though the Chips 1–4 are general-purpose biochips, their applications are still limited by their available input/output ports. For example, Chip 1 has only 6 input/output ports, while the PCR bioassay requires at least 8 input ports (because it has 8 different input reagents). Hence the PCR bioassay cannot be executed on Chip 1, and the corresponding execution time is not available (written as “NA” in the table). From the simulation results presented in Table 6.4, we can find that the proposed general-purpose biochip can be adapted to different bioassays with only a slight increase in the bioassay completion times. Therefore, the proposed general-purpose biochip offers high flexibility when we run various bioassays on a dedicated layout.

Although Chips  $A - D$  and Chips  $E - G$  are bioassay-specific biochip, we still can “force” them to execute various bioassays by applying the scheduling algorithm proposed in Section 6.6. The execution times for running multiplexed bioassay, PCR bioassay, and protein dilution bioassay on Chips  $A - D$  can be found in Table 6.5. The execution times for running multiplexed bioassay, PCR bioassay, and protein dilution bioassay on Chips  $E - G$  can be found in Table 6.6.

By comparing the execution time in Table 6.4, Table 6.5 and Table 6.6, we can find that Chips 1–4 can achieve shorter execution time comparing with Chips  $A - D$  and Chips  $E - G$  in most scenarios. This is because some operations that are implemented in parallel on Chips 1–4 have to be scheduled for sequential implementation

Table 6.3: Comparison of proposed pin-limited biochip, bioassay-specific biochips [65], cross-referencing biochips [37], and direct-addressing biochip.

	Multiplexed bioassay (No. Pins/Time)	PCR (No. Pins/Time)	Protein bioassay (No. Pins/Time)
Proposed heuristic method	19/63 s	19/22 s	18/180 s
Cross router [37][65]	30/132 s	30/26 s	30/195 s
Direct-addressing	59/70 s	62/19 s	52/179 s
Bioassay-specific [65]	25/70 s	14/20 s	27/216 s
ILP-based [130]	11/73 s	6/19 s	12/161 s

Table 6.4: Execution time of bioassays on Chips 1–4.

Biochip Bioassay	Chip 1	Chip 2	Chip 3	Chip 4
Multiplexed bioassay	63 s	65 s	NA	62 s
PCR bioassay	NA	22 s	NA	23 s
Protein bioassay	195 s	221 s	180 s	217 s

Table 6.5: Execution time of bioassays on Chips  $A - D$ .

Protein bioassay	264 s	441 s	220 s	223 s

on Chips  $A - D$  and Chips  $E - G$  due to deadlocks. Therefore, compared with the bioassay-specific biochip in [65], the proposed design has higher flexibility when running various bioassays on the same layout. Compared with the proposed general-purpose biochip, the ILP-based design method can reduce the pin-count by 33.3% to 69.4%. We have noted that there is a trade-off between pin-count and flexibility when the bioassay-specific designs (Chips  $A - D$  [65] and Chips  $E - G$  [130]) and general purpose designs (Chips 1–4) are compared.

Table 6.6: Execution time of bioassays on Chips  $E - G$ .

### 6.7.3 Simulation results on regular array

Next we run bioassays on an  $8 \times 8$  and a  $10 \times 10$  electrode array to evaluate the performance of the proposed general-purpose biochip. The pin-assignment configurations of the  $8 \times 8$  and  $10 \times 10$  biochip are shown in Figure 6.16(a) and Figure 6.16(b), respectively. There are 32 pins assigned to the  $8 \times 8$  layout, and 43 pins assigned to the  $10 \times 10$  layout. The numbers of control pins for the  $8 \times 8$  direct-addressing and cross-referencing biochips are 64 and 16; the numbers of control pins for the  $10 \times 10$  direct-addressing and cross-referencing biochips are 100 and 20, respectively.

The completion times of running bioassays on the direct-addressing biochips, the cross-referencing biochips, and the proposed general-purpose biochips can be found in Table 6.7. Compared to the direct-addressing biochips, the general-purpose biochips can reduce the number of control pins by 50% or more with only a slight increase in the bioassay completion times.

Table 6.7: Execution time of bioassays mapped to an  $8 \times 8$  ( $10 \times 10$ ) electrode array.

Biochip \ Bioassay	Multiplexed	PCR	Protein
Direct-addressing biochip	72 s (72 s)	20 s (20 s)	160 s (142 s)
Cross-referencing biochip [37]	72 s (72 s)	20 s (20 s)	215 s (142 s)
Proposed general-purpose biochip	72 s (72 s)	24 s (20 s)	179 s (157 s)

Table 6.7 shows that for the protein dilution bioassay, the execution time on the  $8 \times 8$  cross-referencing biochip is 20% longer than that for the proposed  $8 \times 8$  pin-limited biochip; for multiplexed bioassay and PCR bioassay, the execution times on these two biochips are almost the same. For the  $10 \times 10$  array shown in Table 6.7, the cross-referencing biochip leads to lower completion time for the protein assay.

However, cross-referencing biochips require special electrode structures (two electrodes per unit cell), which introduce fabrication challenges and additional processing steps [6]. As a result, the fabrication cost for cross-referencing biochip is likely to be higher than biochips without two electrodes per unit cell. For low-cost disposable chips, it is arguable whether cross referencing is always the right solution due to higher fabrication cost.

Finally, we present a comparison between the lower bound on the number of pins predicted by Theorem 6.4.2, the exact optimization results obtained using ILP model, and the results obtained using the heuristic procedure. Note that the lower bound on the number of pins may not always be achievable in practice and correspond to an actual pin-assignment configuration. On the other hand, the ILP model and the heuristic procedure can produce the configurations of the layouts. Hence the actual minimum number of required pins that we obtain by the ILP model is either equal to or larger than the lower bound.

Without loss of generality, we use various rectangular layouts as test cases. The results are shown in Table 6.8. The ILP model is solved using Xpress-MP [134],

Table 6.8: Comparison between lower bound, ILP model, and heuristic solution.

Array size	No. pins (lower bound)	No. pins (ILP model)	No. pins (heuristic method)
$3 \times 3$	9	9	9
$5 \times 7$	18	21	23
$7 \times 8$	24	29	30
$8 \times 8$	26	32	32
$9 \times 9$	30	Computationally impractical	40

which is a widely used commercial ILP solver. The tool is run on a server with 64 GB of memory and two quad-core 2.53 GHz Intel Xeon processors. The computing time for the  $8 \times 8$  array is about 5 hours while for a  $9 \times 9$  array, and the solver runs out of memory. The heuristic method is run on a 2.27 GHz Intel i3 Dual core processor with 2 GB of memory. The CPU times are less than 5 minutes for all cases.

## 6.8 Chapter summary and conclusions

We have presented a new method for mapping control pins to electrodes in the design of “general-purpose” (bioassay-independent) digital microfluidic biochips. We have derived necessary and sufficient conditions for pin-assignment to guarantee conflict-free concurrent manipulation of multiple droplets. The manipulation of droplets with different volumes on the biochip is considered. We have also presented a lower bound on the number of control pins required for an electrode array. A graph-theoretic “acceptance test” has been developed for a given pin-assignment. An optimization technique based on ILP has been described to automatically derive conflict-free pin-assignments. The ILP model is not scalable to large designs, but it can be used for partitioned designs and to evaluate the quality of heuristic solutions. We have presented an efficient heuristic approach for mapping control pins to electrodes. The heuristic method has been evaluated using commercial biochips and laboratory pro-

totypes. Compared with previous techniques, the proposed method can reduce the number of control pins and facilitate the “general-purpose” use of digital microfluidic biochips for a wide range of applications.

## Pin-Limited Cyberphysical Microfluidic Biochip

### 7.1 Introduction

On a digital microfluidic biochip, the number of control pins used to drive electrodes is a major contributor to the fabrication cost [6]. The layout of a typical biochip is shown in Figure 7.1(a), it has three regions:

1. **Active region:** where the biochemistry assays are executed; electrodes and on-chip reservoirs are fabricated in this region.
2. **Contact region:** where the contact pads of the input pins are fabricated. Here each contact pad corresponds to one input pin of the biochip. In order to reduce the contact resistance, the area of each pad is usually larger than an electrode [6].
3. **Wire routing region:** where metal wires are fabricated. The wires connect electrodes to the contact pads of the input pins.

From Figure 7.1(a), it is evident that most area of the biochip is occupied by the connection wires and contact pads. Therefore, the area and the fabrication cost of a

FIGURE 7.1: (a) Layout of a biochip. The biochip has three regions: the region for fabricating electrodes and on-chip reservoirs, the region for wire routing, and the region for fabricating contact pads of input pins (Figure Courtesy: Bang-Ning Hsu, Duke University); (b) side view of the substrate and bottom layer for the two-metal-layer biochip [135][24]; (c) side view of the interconnection between an electrode and its corresponding contact pad.

biochip will increase when the number of the input pins increases.

In order to reduce the number of input pins in biochips, several design methods for pin-limited biochips have been presented in the literature. These design methods map a larger number of electrodes to a small number of control pins according to: (i) the specific synthesis result of a bioassay (i.e., bioassay-specific design

for pin-assignment configurations) [130], or (ii) the arrangement of electrodes on the biochip (i.e., application-independent design for pin-assignment configurations) [37; 136; 137].

In particular, the design method proposed in [136][137] generates an application-independent pin-assignment configuration with a minimum number of control pins. Compared with the bioassay-specific pin-assignment algorithms [130], the method in [136][137] can reduce the number of control pins and facilitate the “general-purpose” use of digital microfluidic biochips for a wider range of applications; each general-purpose pin-limited biochip can be used to perform various target bioassays.

In a cyberphysical microfluidic system, the control software may have to dynamically adjust the schedules of fluid-handling operations as well as the routing paths of droplets. Different bioassays can execute on the same biochip, general-purpose pin-limited biochips [136][137] are good candidates as hardware platforms for low-cost cyberphysical microfluidic systems.

However, despite the flexibility of general-purpose pin-limited biochips, the routability of metal wires in such chip has remained an open problem until now [136][137].

In order to solve the wire-routing problem and reduce the cost of the cyberphysical microfluidic system, in Section 7.2 we first discuss the wire-routing solution for general-purpose pin-limited biochips based on the two-metal-layer fabrication technique developed in recent years [135][24]. Next, we discuss the specific design flow for pin-limited cyberphysical biochips in Section 7.3. Simulation results for three experimental bioassays are discussed in Section 7.4. Finally, conclusions are drawn in Section 7.5.

The key contributions and benefits of this work are as follows:

1. We present a design flow for pin-limited cyberphysical biochip that can further reduce the cost of a cyberphysical microfluidic system.

2. We propose the wire-routing method for pin-limited biochips based on a two-metal-layer fabrication technique [135][24]. The method guarantees that for the commonly used pin-limited biochips, feasible wire-routing solutions can always be derived.

## 7.2 Wire routing for general-purpose pin-limited biochips

For a biochip fabricated using the two-metal-layer technique of [24][135], the side view of the substrate and the lower plate are shown in Figure 7.1(b).

In the active region of the layout, the biochip has one metal layer for fabricating electrodes (i.e., the 1<sup>st</sup> Chromium layer shown in Figure 7.1(b)), and another metal layer for wire routing (i.e., the 2<sup>nd</sup> Chromium layer shown in Figure 7.1(b)); these two metal layers are isolated by SiO<sub>2</sub>. Under each electrode, there is an aluminum via that connects the electrode to its corresponding routing wire.

Similarly, in the contact region of the layout, the 1<sup>st</sup> metal layer is used to fabricate the contact pads of the input pins. For each contact pad, there is an aluminum via that connects the contact pad to the corresponding routing wire (which is fabricated by the 2<sup>nd</sup> metal layer). The side view of the interconnection between the electrode and the corresponding contact pad is shown in Figure 7.1(c). By using the two-metal-layer fabrication technique, electrodes in a large array can be connected to their corresponding input pins.

Assume that we have already derived the pin-assignment configuration for a  $W \times H$  electrode array, and the electrodes are mapped to  $P$  pins. Based on the existing two-metal-layer fabrication technique [24][135], the wire routing solution of the pin-limited biochip can be derived using the following steps.

1. **Adding “routing rings” in the wire routing region.** In the wire routing region, “routing rings” are fabricated using the 1<sup>st</sup> metal layer, as shown in

FIGURE 7.2: (a) An electrode array and “routing rings” for Pins 1 to  $P$ ; (b) a large electrode array that is partitioned into four parts. The wire routing solution for these parts can be derived separately; (c) top view of an electrode sub-array and the underneath routing wires on the direction which is parallel with one edge of the array; (d) top view of an electrode and the underneath routing wires.

Figure 7.2(a). Each routing ring is assigned to one control pin of the biochip, and all the routing rings are axis-parallel rectangles. The total number of fabricated routing rings is  $P$ . The edges of any two rectangles do not intersect, and the routing rings are electrically isolated from each other.

2. **Partitioning an electrode into four parts.** A large electrode array can be “equally” partitioned into upper left, upper right, lower left, and lower right sub-arrays, as shown in Figure 7.2(b). The wire routing for these four sub-arrays are derived separately. In the active region, routing wires in different sub-arrays do not interference with each other.

**3. Connecting electrodes to routing rings.** Based on the pin-assignment configuration, electrodes are connected to their corresponding routing rings. An example is as follows. We assume that the electrode array shown in Figure 7.2(c) is the upper left sub-array of the electrode array shown in Figure 7.2(b). In this sub-array, three electrodes are assigned to be connected to Pin 1. The vias at the centers of these three electrodes electrically connect the electrodes to three routing wires. As shown in Figure 7.2(c), routing wires of these three electrodes intersect with the routing ring for Pin 1. At these crosspoints, vias are added to electrically connect the routing wires with the routing ring for Pin 1. Using this method, all the electrodes that are assigned to Pin 1 are connected to the routing ring for Pin 1.

In the similar manner, all electrodes that are assigned to Pin  $p$  ( $1 \leq p \leq P$ ) are connected to the routing ring for Pin  $p$ .

In order to simplify the wire-routing solution and to avoid any interference between two metal wires on the two-metal-layer biochip, all routing wires are aligned parallel to the edge of the electrode array (in either the direction of  $x$ -axis or  $y$ -axis), as shown in Figure 7.2(c).

**4. Connecting routing rings to input pads.** In the contact region,  $P$  contact pads are fabricated using the 1<sup>st</sup> metal layer, and each routing ring is connected to its corresponding contact pad. The connection wires are fabricated using the 2<sup>nd</sup> metal layer.

Among the above steps, we note that the routability of a pin-limited biochip is determined in Step 3, i.e., if there is enough space underneath each electrode to place the parallel routing wires, the pin-limited biochip is routable. As shown in Figure 7.2(c), at the edge of the sub-array that is perpendicular to the routing wires, the electrodes have the maximum number of routing wires underneath them (i.e.,

the four electrodes at the first row of the  $4 \times 4$  sub-array each has four routing wires underneath it). Similarly, for a  $W_s \times H_s$  ( $W_s \neq H_s$ ) rectangular sub-array, if the routing wires are aligned parallel to the longer edge of the rectangle, the maximum number of routing wires fabricated underneath the electrodes is  $\max\{W_s, H_s\}$ ; if the routing wires are aligned parallel to the shorter edge of the rectangle, the maximum number of routing wires fabricated underneath the electrodes is  $\min\{W_s, H_s\}$ . As the orientation of routing wires can be parallel to either the longer or shorter edge of the sub-array, we will always align routing wires parallel to the shorter edge of the rectangle when designing the wire-routing solution for the  $W_s \times H_s$  rectangular sub-array. Hence, the maximum number of routing wires need to be fabricated underneath electrodes in the sub-array is  $\min\{W_s, H_s\}$ .

Therefore, based on the size of the electrode array, as well as the geometric sizes of electrodes, routing wires, and vias, we can determine whether a pin-limited biochip has a feasible wire routing solution. For a  $W \times H$  pin-limited biochip, the sufficient condition for the existence of its wire routing solution can be derived as follows.

The top view of an electrode and the underneath routing wires are shown in Figure 7.2(d). Here we assume that the diameter of the via is  $D_{\text{via}}$ , the width and length of each electrode are both  $D$ , and the width of a routing wire is  $T_w$ . In order to prevent electrical shorting of the two wires, the gap between them is  $T_{\text{bw}}$ . Therefore, the average “occupied” width of each routing wire can be estimated as  $(T_w + T_{\text{bw}})$ .

As shown in Figure 7.1(b) and Figure 7.2(d), there is a via at the center of each electrode. Since the routing wire cannot overlap with the via, the “effective width” under each electrode that can be used for aligning routing wires is estimated as  $(D - D_{\text{via}})$ . Therefore, the maximum number of routing wires that can be fabricated underneath an electrode can be estimated as  $\lfloor \frac{D - D_{\text{via}}}{T_w + T_{\text{bw}}} \rfloor$ , where  $\lfloor * \rfloor$  represents the largest integer not greater than “\*”.

As discussed above, a  $W \times H$  electrode array can be “equally” partitioned into

FIGURE 7.3: The design flow for pin-limited cyberphysical biochips.

four sub-arrays, and the size of the maximum sub-array is  $\lceil \frac{W}{2} \rceil \times \lceil \frac{H}{2} \rceil$ , where  $\lceil * \rceil$  represents the smallest integer not less than “\*”.

Therefore, a  $W \times H$  two-metal-layer biochip is routable when:

$$\min(\lceil \frac{W}{2} \rceil, \lceil \frac{H}{2} \rceil) \leq \left\lfloor \frac{D - D_{\text{via}}}{T_w + T_{\text{bw}}} \right\rfloor.$$

The typical values for  $D$ ,  $D_{\text{via}}$ ,  $T_w$ ,  $T_{\text{bw}}$  are  $1000 \mu m$ ,  $200 \mu m$ ,  $20 \mu m$ , and  $20 \mu m$ , respectively [24][135]. Therefore, if  $W \leq 40$  or  $H \leq 40$ , the pin-limited biochip fabricated by two-metal-layer technique is routable. For most of the benchmark bioassays that are extensively discussed in literature, the sizes of the required electrode arrays are smaller than  $40 \times 40$ . Hence for the commonly used pin-limited biochips, we can derive feasible wire routing solutions by Steps 1 ~ 4 proposed above.

### 7.3 Design flow for pin-limited cyberphysical biochips

For a given  $W \times H$  electrode array without pin-assignment, the heuristic algorithm proposed in [136][137] can first derive a pin-assignment configuration that is application-independent. Next, if  $W \leq 40$  or  $H \leq 40$ , by applying Steps 1 ~ 4 proposed in Section 7.2, we always can find a feasible wire routing solution for this pin-limited biochip.

For any given bioassay, by applying the operation-dependency-aware synthesis algorithm and the droplet-routing approach described in Section 5.3 and Section 5.4, the synthesis result of the bioassay on a  $W \times H$  direct-addressing biochips can be derived. The synthesis result is defined as the “initial synthesis results”.

Next, the scheduling algorithm proposed in [137] is used to adjust the “initial synthesis result” (derived on a direct-addressing biochip) according to the pin-assignment configuration of the layout. Finally, the synthesis results of the bioassay on the pin-limited biochip can be derived, i.e., the bioassay can now be executed on the low-cost pin-limited biochip. The flowchart for the complete design flow is shown in Figure 7.3.

### 7.4 Simulation results

#### 7.4.1 Results derived by the operation-interdependency-aware synthesis approach

In Section 5.5.3, we have mapped bioassays to direct-addressing biochips with different sizes. The corresponding completion times of bioassays in dilution/mixing (D/M) phases and transportation (T) phases on the direct-addressing biochips are shown in Table 5.3.

As discussed in Section 7, we can map bioassays to pin-limited general purpose biochips proposed in [136][137]. The pin-assignment configurations for  $8 \times 8$ ,  $9 \times 9$ ,  $10 \times 8$ , and  $12 \times 8$  electrode arrays are shown in Figure 7.4. Compared with the di-

	$9 \times 9$	45	133	178
	$10 \times 8$	48	165	213
	$12 \times 8$	45	189	234

rect-addressing scheme, the design of pin-limited general-purpose biochips can reduce the pin-counts by 50.0% to 65.8%.

The synthesis results for executing bioassays on direct-addressing biochips are defined as “initial results”. By applying the scheduling algorithm proposed in [137] on

FIGURE 7.5: The relationship between completion time of bioassays and  $f_T$  on the  $8 \times 8$  biochip shown in Figure 7.4(a).

the initial results, we derive the synthesis results for bioassays. Hence the bioassays can be mapped to the general-purpose pin-limited biochips shown in Figure 7.4. The corresponding completion times of bioassays in D/M phases and T phases on these pin-limited general-purpose biochips are shown in Table 7.1. Here the completion time of D/M phases is defined as the sum of time spans for all the D/M phases in the bioassay. The completion time of T phases is defined as the sum of time spans for all the T phases in the bioassay. The working frequency of T phase is also set as 1 Hz.

#### 7.4.2 Completion time with multiple clock frequencies

In Section 5.5.6 we present the relationship between the bioassay completion time and the clock frequency of the droplet transaction phase on a biochip with multiple working frequencies. If the bioassays are executed on the  $8 \times 8$  pin-limited electrode array shown in Figure 7.4(a), the relationship between completion time of bioassays and the clock frequency of the T phase is shown in Figure 7.5. The execution times for exponential dilution and interpolation dilution bioassays on the pin-limited biochip can be greatly reduced by increasing  $f_T$ . For example, when  $f_T$  increases from 1 Hz

to 10 Hz, the execution time for exponential dilution bioassay is reduced from 297 seconds to 134 seconds.

From the simulation results, we find that when the clock frequency of the T phase increases, the completion time of PCR bioassay on the pin-limited biochip does not decrease significantly. This is because the time for droplet transportation in the PCR bioassay is relatively low.

## 7.5 Chapter summary and conclusions

In this chapter, we discuss the method for metal wire routing on pin-limited biochip. The proposed method can guarantee that, with two-metal-layer fabrication technique, all the widely-used pin-limited biochips are routable. In order to reduce the cost of the cyberphysical biochip, we also propose the design flow for pin-limited cyberphysical microfluidic biochip. The simulation results show that, the proposed method can reduce the number of control pins and facilitate the “general-purpose” use of cyberphysical digital microfluidic biochips for a wide range of applications.

## Conclusions and Future Work

### 8.1 Thesis contributions

In this thesis work, we have proposed a set of design techniques for cyberphysical microfluidic biochips. Contributions include design methods that consider timing uncertainties in operations, optimization to handle droplets with various volumes, layout optimization of cyberphysical PCR biochips, and a design flow for cyberphysical pin-limited microfluidic biochips. Compared to prior design methods, this thesis has led to a computer-aided design flow that considers physical constraints and enables the development of cyberphysical biochip systems.

This thesis presents the first step towards physical-aware optimization and control software design. We have developed an algorithm for droplet tracking based on pictures captured by CCD cameras, and a reliability-driven error recovery strategy. Using feedback from sensors, the control software can determine whether there are errors on the biochip. The control software discards the region where an error has occurred to ensure reliable chip operation. We have also developed a re-synthesis method for cyberphysical biochip, which can dynamically alter the schedule of fluid-

handling operations based on sensors' feedback.

An important contribution of this thesis includes a dictionary-based error recovery method for low-cost portable cyberphysical microfluidic systems. In order to derive error dictionaries, a technique has been developed for realistic fault simulation. By utilizing error dictionaries, we can achieve a cost-effective implementation of cyberphysical systems to recover from errors that occur during chip usage.

In order to mimic the behavior of faulty fluid-handling operations, we have developed a fault simulation framework that can integrate data collected from real experiments. In prior work, error recovery and synthesis were based on the assumption that all operations have the same failure probability, but this assumption may not reflect reality. In order to address this problem, we have developed failure models of biochips based on real data, and used these models to guide fault simulation.

By considering the physical constraints in cyberphysical microfluidic system, we have developed a layout optimization technique for cyberphysical PCR biochips. A statistical model for DNA amplification has been introduced. The module is used to predict whether the droplet has enough DNA strands to carry out the PCR, and it helps us to improve the efficiency of PCR on cyberphysical biochips. We have developed a layout algorithm that considers interference between the on-chip elements such as reservoirs, sensors and thermal units. An optimization algorithm has been developed to minimize the area and electrode count of the biochip and satisfy proximity constraints. Several real-life bioassays have been used to demonstrate that the proposed design method reduces the overall mixing/dilution/detection time for a given bioassay.

In order to overcome the inherent variability and randomness of biological/chemical processes and improve the quality of product droplets, this thesis has also presented a synthesis algorithm for bioassays that is capable of taking into account uncertainties inherent in biochemical reactions. An "operation-interdependence-aware" synthesis

algorithm has been developed — the first on-chip biochemistry synthesis procedure that does not use the module library as a design guideline. Using this algorithm, the dependence on characterization can be reduced. The algorithm leads to a design approach that considers completion-time uncertainties for fluidic operations, hence the accuracy of fluidic operations is also improved. The proposed approach explicitly considers the transportation of droplets. Hence it guarantees the feasibility of droplet-routing, and determines the transportation path for each droplet. In order to reduce the execution time of the bioassay without additional degradation of electrodes or hardware cost, the design of microfluidic biochips using multiple clock frequencies has also been considered. An on-line droplet-routing method with low computational complexity has been developed. The response time of the resulting cyberphysical system is negligible. Therefore, the degeneration of intermediate products in the bioassay can be avoided.

To minimize the number of control pins and simultaneously maximize the flexibility of biochips, we have developed design techniques for general-purpose pin-limited biochips. A graph model for analyzing pin-assignment configurations of a biochip has been developed. Based on the graph model, we have developed a heuristic algorithm for the design of pin-assignment configuration, devised an acceptance test, and developed a scheduling algorithm for fluid-handling operations. The manipulation of droplets with various volumes has also been considered, and new design constraints associated with the processing of large droplets have been discussed. The metal wire routing method for pin-limited has been investigated. Finally, by combining the design algorithms for general-purpose pin-limited biochip and cyberphysical microfluidic biochips, a design flow for cyberphysical pin-limited biochips has been developed.

In summary, this thesis work has been centered on the design and optimization of a comprehensive algorithmic infrastructure for a cyberphysical biochip system. A

series of related design problems for cyberphysical microfluidic systems have been addressed, including uncertainty-aware synthesis, dynamic error recovery, layout optimization, pin-count minimization, and optimization for cyberphysical pin-limited biochips. This thesis has therefore led to powerful design tools for cyberphysical microfluidic biochips and can serve as a bridge between theoretical design algorithms and realistic applications of biochips.

## 8.2 Future research directions

The contents of this thesis open up a number of exciting directions for research in the emerging area of automated biochip design. These new directions are summarized below.

### *8.2.1 Optimization of droplet monitoring systems on cyberphysical biochips*

In a cyberphysical digital microfluidic system, the monitoring of droplets is vitally important. Researchers often use cameras fixed on the hardware platform to simultaneously monitor multiple operations on the biochip [21]. From the captured images, the volumes and concentrations of the droplets can be determined at each step of the bioassay, and the time required to complete the dilution/mixing processes on the biochip can be measured precisely [21]. However, misleading results concerning the completion of these processes may be derived if only the top view is used for monitoring the fluid-handling operations. For example, a fluorescein droplet and a non-fluorescein droplet are merged together for 10 seconds, and cameras capture images of the mixed droplet from top and side views, as shown in Figure 8.1 [21]. From the top view, it is observed that the fluorescent reagent has been homogeneously distributed in the merged droplet, i.e., the mixing procedure may appear to be complete. However, from the side view, it is apparent that the merged droplet has multiple layers, i.e., the fluorescein droplet and the non-fluorescein droplet are over-

FIGURE 8.1: Top and side views captured after merging a fluorescein droplet with a non-fluorescein droplet for 10 seconds [21].

FIGURE 8.2: (a) Droplets 1 and 2 are invisible from side view if the camera is fixed at Position 1. Droplets 2 and 3 are invisible from side view if the camera is fixed at Position 2; (b) set at different initial positions for Droplets 3 and 4; (c) the movements of Droplets 1 and 2 in the  $x$  direction.

lapping each other rather than being well mixed. From this example, we know that it is essential to monitor cyberphysical microfluidic biochips, using both top and side views simultaneously. Thus, two cameras must be fixed onto the hardware platform so that images of the droplets can be acquired from two different perspectives.

When multiple droplets are manipulated concurrently on the biochip, the visibility of the droplets for the side-view assessment should be considered. An example is shown in Figure 8.2(a). We assume that droplets 1 ~ 4 are being mixed concurrently in four mixers on the biochip.

The directions in which droplets 1 ~ 4 are moving in the mixing procedure are indicated by the arrows. We assume that these four mixing operations start at the same time with the droplets moving in the same direction. The initial positions of droplets 1 and 3 are in the same row of the electrode array, and the initial positions of droplets 2 and 4 are in the same row of the electrode array. When we project the movements of droplets 1 and 3 on the  $y$ -axis, they will always overlap each other during the mixing procedure. Therefore, if the camera is fixed at position 1 and we acquire side-view images of these four droplets, droplet 1 will always be hidden behind droplet 3, i.e., droplet 1 is “invisible” to the monitoring system. Similarly, droplet 2 will always be hidden behind droplet 4, and it is also invisible to the monitoring system.

If the camera is fixed at position 1 and monitors these four droplets from the side, droplets 2 and 4 will always be invisible to the monitoring system. This situation must be avoided in order to monitor the mixing procedures of all of the droplets on the biochip simultaneously.

To solve this problem, we can set different initial positions for droplets 1 and 2, as shown in Figure 8.2(b). When projecting the movements of droplets 1 and 2 on the  $x$ -axis, the relationship between time and the positions of these two droplets is shown in Figure 8.2(c). At times 1, 2, 3, and 4, the positions of droplets 1 and 2 do not overlap each other, so both of these droplets can be photographed by the camera.

By projecting the movements of droplets onto the  $x$  or  $y$  axis, the maximum number of droplets that can be observed from the side view can be calculated. An example is as follows. Assume there are  $1 \times 4$  mixers on the biochip, and the projections of these mixers on the  $y$ -axis overlap each other. Then by setting different initial positions and different initial moving directions, we can determine that the maximum number of droplets that can be observed in parallel is six. In the synthesis algorithm of a microfluidic biochip, this constraint on the maximum number of

FIGURE 8.3: Schematic diagram showing a side-view of the hot-air thermocycler with optical setup [138].

operations that can be executed in parallel must be considered.

### 8.2.2 Optimization of 3-dimensional PCR microfluidic biochips

In Chapter 5, we discussed the optimization of the layout design of a PCR biochip. This thesis has only considered planar digital microfluidic biochips, i.e., we assumed that all of the components of the biochip, including the electrode array, on-chip reservoirs, optical sensors, and the heater, are fabricated on the surface of the substrate.

With the development of an appropriate fabrication technique, the design of “3-dimensional PCR biochip” has been proposed [138]. For some biochips, the heater may be placed under the biochip rather than being fabricated on the same layer with the reservoirs; also, the detectors may be placed above or under the biochip (on the top or bottom plate of the biochip) rather than being placed on the same flat with the reservoirs. Figure 8.3 shows the structure of a 3D PCR biochip [138]. Therefore, optimization of the placement of the modules on PCR biochips must be viewed as a 3-dimensional, module-placement problem.

### 8.2.3 Synthesis with a decision-tree structure

On a cyberphysical microfluidic biochip, we can potentially implement a bioassay with a decision-tree architectures. Decision-tree architectures will enable new functions for a biochip, such as biochemical analysis for unknown analytes. This pro-

cedure can be described as follows. Droplets with an unknown sample can be used as an input to the biochip. Then, the droplet will be sent to a series of checkpoints and the droplet's constituents are checked step by step. Based on the detection result at each checkpoint, the biochip will determine the next operations that will be implemented on the droplet.

Before a bioassay is executed, all possible optimized actuation sequences, corresponding to different root-to-leaf paths in the decision tree, are generated by the control software and saved in memory. In a real experiment, the actuation sequences to be applied to the chip are chosen based on the feedback from on-chip sensors.

#### *8.2.4 Integration of capacitive sensors in pin-limited biochips*

In [139], the authors presented the first demonstration of a cyberphysical system on real biochips. Capacitive sensors are integrated into a direct-addressing biochip to monitor the movements of droplets. Here we propose the integration of a capacitive sensor into a pin-limited general-purpose biochip (Chapter 6) and discuss the corresponding algorithm for monitoring droplets.

A schematic diagram of the system used to measure the capacitance of a digital microfluidic biochip is shown in Figure 8.4(a). Each unit of the digital microfluidic biochip has a pair of plates; the upper plate is a common ground for all the unit cells and the lower plates are connected to corresponding control pins.

There is a capacitance associated with a pair of electrodes in each unit cell of biochips. In order to measure the capacitance, the unit cell of a biochip is connected to a resistance to establish an resistor-capacitor (RC) circuit. By measuring oscillation frequency of the RC circuit, we can derive the capacitance of the unit cell on the biochip. When a droplet is moved to a pair of electrodes, the capacitance corresponding to this pair of electrodes will change. Hence by comparing the calibrated capacitance of the unit cell with the measured capacitance, we can determine the

FIGURE 8.4: (a) The schematic for the system of capacitance measurement for digital microfluidic biochips [140]; (b) equivalent circuit for electrodes that are controlled by the same pin.

presence of a droplet.

Next, we consider capacitive sensors that are integrated with pin-limited biochips. As shown in Figure 8.4(b), there are four unit cells of EWOD actuators. In order to use Pin A to apply control signals on unit cells 1 and 4 together, their lower plates, i.e., electrodes  $E_1$  and  $E_4$ , are connected by a metal wire. Hence the unit cells of the EWOD actuators 1 and 4 can be modeled as two capacitors  $C_1$  and  $C_4$  that are connected in parallel, as shown in Figure 8.4(b). The capacitive sensor can measure the value of the two capacitors together, but it cannot measure the capacitance values of  $C_1$  and  $C_4$  separately. In this scenario, the capacitive sensor for the pin-limited biochip can only detect the absence/presence of droplets on the electrodes that are connected to Pin A, but it cannot identify the exact position of the droplet.

Hence the results provided by capacitive sensors in pin-limited biochips may be misleading. An example is shown in Figure 8.6. Electrodes A and B are both connected to Pin 1, and Electrode B is a checkpoint for droplet monitoring. At time  $t$ , the expected positions of the droplets are shown in Figure 8.5(a). However,

FIGURE 8.5: (a) The expected positions of droplets; (b) wrong positions of droplets which still can get “correct” sensing result; (c) an example of “capacitance transfer” from control Pin A to Pin B.

suppose that due to physical defects on the chip, a droplet is stuck at Electrode A, and another droplet, which is scheduled to be moved to Electrode B, is also stuck at another electrode, as shown in Figure 8.5(b). Note that Electrodes A and B are connected in parallel. Therefore, for the case shown in Figure 8.5(a), the capacitance  $C_1$  measured by the sensor can be expressed as:  $C_1 = C_{absence} + C_{presence}$ , where  $C_{absence}$  is the capacitance due to unit cells without any droplet, and  $C_{presence}$  is the capacitance due to unit cells with droplets.

For the case shown in Figure 8.5(b), the capacitance measured by the sensor can also be written as:  $C_2 = C_{absence} + C_{presence}$ .

Hence the capacitive sensor will provide the same results for the cases shown in Figure 8.5(a) and Figure 8.5(b). In this situation, even though errors have occurred on the biochip, these errors cannot be detected by the capacitive sensor. Thus, this example shows that we may get misleading results from the checkpoints for

pin-limited biochips.

In this section, we propose a method to solve this problem by assigning a capacitive sensor to each control pin of the biochip. We show that, for the general-purpose pin-limited biochip described in Chapter 6, we can track the movements of multiple droplets simultaneously based on the feedback from capacitive sensors. The theoretical calculation is introduced below.

According to the design constraints of a general-purpose pin-limited biochip, when a droplet is moved from one electrode to another, the capacitance of the droplet will be “transferred” from one pin to another pin, as shown in the following example. Figure 8.5(c) shows that one droplet is moved from  $E_1$  to  $E_2$  and that  $E_1$  and  $E_2$  are controlled by Pin A and Pin B, respectively. When there is no droplet on the electrodes, assume that the capacitances associated with Pin A and Pin B are  $C_{A_0}$  and  $C_{B_0}$ , respectively; and when there is a droplet on an electrode, assume the capacitances associated with Pin A and Pin B are  $C_{presence_A}$  and  $C_{presence_B}$ , respectively. So at the time point  $t = t_0$ , the droplet stays on  $E_1$ , and the capacitance associated with Pin A and Pin B ( $C_A(t_0)$  and  $C_B(t_0)$ ) can be written as:

$$C_A(t_0) = C_{presence_A},$$

$$C_B(t_0) = C_{B_0}.$$

At the time point  $t = t_0 + 1$ , the droplet has moved from  $E_1$  to  $E_2$ , so the capacitance associated with Pin A and Pin B ( $C_A(t_0 + 1)$  and  $C_B(t_0 + 1)$ ) can be written as:

$$C_A(t_0 + 1) = C_{A_0},$$

$$C_B(t_0 + 1) = C_{presence_B}.$$

From the above equations, we find that the movement of a droplet can lead to changes in the capacitance for a pair of control pins. According to the design requirements of the general-purpose pin-limited biochip (introduced in Chapter 6),

each possible combination of control pins appears no more than once in any layout. Based on the pin-assignment configuration of the biochip and the pairs of pins that indicate capacitance change, we can identify the position of droplets on the chip. This approach for droplet localization and monitoring can be examined in more detail in future work.

### 8.2.5 *Design of microfluidic biochips with on-chip logic circuits*

Recent developments in the techniques used to fabricate biochips have enabled the integration of logic circuits and electrowetting-on-dielectric (EWOD) devices. Figure 8.6(a) shows an EWOD electrode array (boxed area) controlled by a backplane complementary metal-oxide-semiconductor (CMOS) circuit [141], and Figure 8.6(b) shows the logic circuit integrated on an active-matrix electrowetting-on-dielectric (AM-EWOD) device [54].

The capability of integrating an electrode array and control logic may result in some exciting improvements in the design of digital microfluidic biochips. For example, for pin-limited biochips, integrated CMOS multiplexers can be fabricated on the electrode array to control the pin-assignment configuration of the biochip. Therefore, a biochip may dynamically change its pin-assignment configuration during the execution of a bioassay. With this controllability on pin-assignment biochips, the pin-count of the biochips and the completion time of bioassays may be reduced further. Thus, more powerful “general-purpose pin-limited biochips” can be achieved.

### 8.2.6 *Design of fluidic-constraint-aware cyberphysical microfluidic biochip*

When bioassays are run on digital microfluidic biochips, there are some fluidic constraints on the movement of droplets. For example, if two droplets are not scheduled to be mixed together, then they should never come in contact with each other. In previous designs, these constraints are set when we generate the synthesis result, i.e.,

FIGURE 8.6: (a) EWOD electrode array (boxed area) controlled by backplane complementary metal-oxide-semiconductor (CMOS) circuit [141]; (b) logic circuit on an active matrix electrowetting on dielectric (AM-EWOD) device [54].

in the ideal case, the synthesis result of a bioassay should guarantee that all of the fluidic constraints are satisfied.

All synthesis algorithms have an underlying assumption, i.e., that all of the droplets move at the same speed when the same voltage is applied. However, the experimental results demonstrate that different kinds of droplets move at different speeds with the same applied voltage. For example, a droplet of a dilute solution of  $\text{Na}_2\text{CO}_3$  moves at twice the speed a droplet of a dilute solution of  $\text{CaCl}_2$  when the same voltage is applied [24]. For droplets that contain the same solution with different concentrations, their movement speeds can also be different.

Due to the differences in the speeds at which droplets move, the synthesis results cannot provide a 100% guarantee that fluidic conflicts will be avoided because some droplets may move slower or faster than expected. Thus, the undesirable “collisions” of droplets may occur if the speeds at which the droplets move are different from the expected speeds.

To solve this problem, on-chip capacitive sensors can be used to create an “intelligent” system that can automatically adjust the movements of the droplets when a violation of the fluidic constraints may occur. As introduced in Chapter 1, with on-chip capacitive sensors, we can precisely locate droplets and measure their speeds. If the measurement results indicate that a “collision” of two droplets will occur, the sensor sends a “stop” signal to one of the droplets. Then, the droplet will be required to stay at its current position to avoid the unwanted violation of fluidic constraints.

Another possible application for the intelligent cyberphysical biochip is the development of a power-saving biochip. In the biochips described in the literature, all droplets are driven by the same voltage, and their corresponding charging times of the electrodes are the same. However, as the “mobility” of droplets vary, a fixed charging time for driving all the droplets may be unnecessarily long for some droplets. The excessive charging time for electrodes may increase the degradation of electrodes [24]. To avoid this problem, a cyberphysical microfluidic biochip may dynamically adjust the voltage and charging time for driving droplets according to their “mobilities”. In this way, the reliability as well as the lifetime of biochips is improved, while the power-consumption is reduced.

# Biography

- Yan Luo
- Place of birth: Anlu, Hubei Province, China
- Date of birth: April 23, 1988

## EDUCATION

- Ph.D., Duke University, USA, 11/2013.
- M.S., Duke University, USA, 05/2012.
- B.S., Tsinghua University, China, 07/2010.

## PROFESSIONAL EXPERIENCE

- Senior Hardware Engineer, Oracle, Santa Clara, CA 05/2013-present
- Hardware Engineer Intern, Oracle, Santa Clara, CA 05/2012-08/2012
- Hardware Intern, Qualcomm Inc., Bridgewater, NJ 06/2011-08/2011
- Research Assistant, Duke University, Durham, NC 08/2010-05/2013

## SELECTED PUBLICATIONS

### **Book Chapter**

- K. Chakrabarty, Y. Luo and K. Hu “Adaptive and Reconfiguration-Based Error Recovery in Cyberphysical Biochips”, In K. Iniewski and S. Carrara, ed., *Handbook of Bioelectronics: Directly Interfacing Electronics and Biological Systems*, Cambridge University Press, 2013.

### **Journal Papers**

- Y. Luo, K. Chakrabarty and T.-Y. Ho, “Real-time error recovery in cyber-physical digital-microfluidic biochips using a compact dictionary”, accepted for publication in *IEEE Transactions on Computer-Aided Design of Integrated Circuits and Systems*, vol. 32, Issue 12, pp. 1839-1852, 2013.

- Y. Luo and K. Chakrabarty, “Design of pin-constrained general-purpose digital microfluidic biochips”, *IEEE Transactions on Computer-Aided Design of Integrated Circuits and Systems*, vol. 32, Issue 9, pp. 1307-1320, 2013.
- Y. Luo, K. Chakrabarty, and T.-Y. Ho, “Error recovery in cyberphysical digital-microfluidic biochips”, *IEEE Transactions on Computer-Aided Design of Integrated Circuits and Systems*, vol. 32, Issue 1, pp. 59-72, 2013.

### Conference Papers

- Y. Luo, B. Bhattacharya, T.-Y. Ho and K. Chakrabarty, “Optimization of polymerase chain reaction on a cyberphysical digital microfluidic biochip”, *Proc. IEEE/ACM International Conference on Computer-Aided Design*, pp. 622-629, 2013.
- Y. Luo, K. Chakrabarty and T.-Y. Ho, “Design of cyberphysical digital-microfluidic biochips under completion-time uncertainties in fluidic operations”, *Proc. ACM/IEEE Design Automation Conference*, pp. 44-50, 2013.
- Y. Luo, K. Chakrabarty, and T.-Y. Ho, “Dictionary-based error recovery in cyberphysical digital-microfluidic biochips”, *Proc. IEEE/ACM International Conference on Computer-Aided Design*, pp. 369-376, 2012.
- Y. Luo and K. Chakrabarty, “Design of pin-constrained general-purpose digital microfluidic biochips”, *Proc. ACM/IEEE Design Automation Conference*, pp. 18-25, 2012.
- Y. Luo, K. Chakrabarty, and T.-Y. Ho, “A cyberphysical synthesis approach for error recovery in digital microfluidic biochips”, *Proc. IEEE/ACM Design, Automation and Test in Europe Conference*, pp. 1239-1244, 2012.
- Z. Zhang, X. Kavousianos, Y. Luo, Y. Tsiatouhas and K. Chakrabarty, ”Signature analysis for testing, diagnosis, and repair of multi-mode power switches”, *Proc. IEEE European Test Symposium*, pp. 13-18, 2011.
